PHOTOCHEMISTRY AND
PHOTOBIOLOGY**

Contents

Preface.....	xi
Editors.....	xiii
Contributors	xv
1 Industrial Photochemistry.....	1
<i>André M. Braun, Günther H. Peschl, and Esther Oliveros</i>	
2 Excilamp Photochemistry.....	21
<i>Thomas Oppenländer</i>	
3 Microphotochemistry: Photochemical Synthesis in Microstructured Flow Reactors	49
<i>Oksana Shvydkiv and Michael Oelgemöller</i>	
4 Photolabile Protecting Groups in Organic Synthesis.....	73
<i>Christian G. Bochet and Aurélien Blanc</i>	
5 Photochemical Key Steps in Organic Synthesis	95
<i>Norbert Hoffmann</i>	
6 Photochirogenesis	125
<i>Cheng Yang and Yoshihisa Inoue</i>	
7 Enantioselective Photoreactions in Solution.....	177
<i>Kerrie A.B. Austin and Thorsten Bach</i>	
8 Spin-Center Shift Reactions.....	201
<i>Pablo Wessig</i>	
9 Photochemistry in Ecosustainable Syntheses: Recent Advances.....	213
<i>Valentina Dichiarante and Stefano Protti</i>	
10 Solar Photochemistry from the Beginnings of Organic Photochemistry to the Solar Production of Chemicals	237
<i>Emma E. Coyle and Michael Oelgemöller</i>	
11 Photochemistry in Alternative Media	249
<i>Tadashi Mori and Yoshihisa Inoue</i>	

12	Cryogenic Matrix Photochemistry	277
	<i>Götz Bucher</i>	
13	Preparative and Mechanistic Semiconductor Photocatalysis	293
	<i>Horst Kisch and Dariusz Mitoraj</i>	
14	Radical Photochemistry	329
	<i>Uta Wille</i>	
15	Recent Advances in the Photoinduced Radical Nucleophilic Substitution Reactions	347
	<i>Maria E. Budén, Sandra E. Martín, and Roberto A. Rossi</i>	
16	Photochemistry of Aryl Halides	369
	<i>Luca Pretali and Angelo Albini</i>	
17	Photochemistry of Phosphate and Sulfonate Esters.....	393
	<i>Davide Ravelli and Maurizio Fagnoni</i>	
18	Stabilized Carbocations Generated by Photoheterolysis	419
	<i>Hans-Werner Abraham</i>	
19	Intermolecular Photochemical Hydrogen Abstraction: Synthetic Applications in Relation to Carbon–Carbon Bond Formation	445
	<i>Niall W.A. Geraghty and Mary Treasa Lohan</i>	
20	Inter- and Intramolecular Photocycloaddition of Aromatic Compounds.....	489
	<i>Hajime Maeda and Kazuhiko Mizuno</i>	
21	Di- π -Methane Rearrangement	511
	<i>Howard E. Zimmerman</i>	
22	Oxa-Di- π -Methane Rearrangement of β,γ -Unsaturated Ketones	527
	<i>V. Jayathirtha Rao and Kolupula Srinivas</i>	
23	Photochemical Bergman Cyclization and Related Photoreactions of Ene-dienes.....	549
	<i>Igor V. Alabugin, Wang-Yong Yang, and Runa Pal</i>	
24	Scope and Limitations of Hula-Twist Mechanism of Photoisomerization.....	593
	<i>Robert S.H. Liu, Yao-Peng Zhao, and Lan-Ying Yang</i>	
25	Fulgimides	607
	<i>Karola Rück-Braun, Kerstin Mayer, Andreas Hebert, and Fabian Michalik</i>	
26	Photoenolization and Its Applications	627
	<i>Petr Klán, Jakob Wirz, and Anna D. Gudmundsdottir</i>	
27	Paternò–Büchi Reaction.....	653
	<i>Maurizio D'Auria</i>	
28	Quinone Photochemistry	683
	<i>Helmut Görner</i>	
29	Photodecarboxylation of Arylacetic Acids	715
	<i>Matthew Lukeman</i>	

30	Photooxygenation, [2+2] and [4+2].....	727
	<i>Maria Rosaria Iesce and Flavio Cermola</i>	
31	Singlet Oxygen-Mediated Allylic Oxidation	765
	<i>Mariza N. Alberti and Michael Orfanopoulos</i>	
32	Photooxygenations of Sulfur Compounds.....	789
	<i>Edward L. Clennan</i>	
33	Porphycenes: Spectroscopy, Photophysics, and Tautomerism	809
	<i>Jacek Waluk</i>	
34	Photochemical Transformations Involving Porphyrins and Phthalocyanines	831
	<i>Natalia N. Sergeeva and Mathias O. Senge</i>	
35	Photochemical Routes for Metal Nanoparticle Synthesis.....	881
	<i>Katherine L. McGilvray and J.C. Scaiano</i>	
36	Photocatalytic Water Splitting.....	911
	<i>Junwang Tang and Alexander J. Cowan</i>	
37	Overview of the Development of Integrated Photocatalytic Adsorbents (IPCA) for Water Treatment Using Titanium Dioxide (TiO ₂) and Activated Carbon	935
	<i>David Keane, Kieran Nolan, Anne Morrissey, Michael Oelgemöller, Shaik Basha, and John Tobin</i>	
38	Molecular Logic Based on Optical Signaling	963
	<i>Uwe Pischel and Joakim Andréasson</i>	
39	Application of Photophysics to the Study of Supramolecular Dynamics	981
	<i>Tamara C.S. Pace and Cornelia Bohne</i>	
40	Photostability of Drugs and Drug Products.....	1003
	<i>Beverley Glass</i>	
41	Computational Photochemistry and Photobiology.....	1029
	<i>Patrick Z. El-Khoury, Igor Schapiro, Mark Huntress, Federico Melaccio, Samer Gozem, Luis Manuel Frutos, and Massimo Olivucci</i>	
42	DNA Fluorescence.....	1057
	<i>Dimitra Markovitsi, Thomas Gustavsson, and Akos Banyasz</i>	
43	Action Spectroscopy: General Problems	1081
	<i>Edward D. Lipson</i>	
44	Action Spectroscopy: Ultraviolet Radiation.....	1093
	<i>Thomas P. Coohill and Francesco Ghetti</i>	
45	Photosensitization: Basic Principles	1105
	<i>Giulio Jori</i>	
46	Photoecology and Environmental Photobiology.....	1117
	<i>Donat-P. Häder</i>	

47	Photoactive Yellow Protein, the Prototype Xanthopsin	1137
	<i>Johnny Hendriks, Marijke Hospes, and Klaas J. Hellingwerf</i>	
48	Photomovements in Eukaryotic Microorganisms.....	1161
	<i>Giovanni Checcucci and Francesco Ghatti</i>	
49	Transport and Sensory Rhodopsins in Microorganisms	1173
	<i>Yuki Sudo</i>	
50	Nonvisual Photosensitivity and Circadian Vision	1195
	<i>Carlo Musio and Silvia Santillo</i>	
51	The Essential Role of Retinoids as Ligands for Visual Pigment Formation in and Survival of Cone Photoreceptors	1211
	<i>Peter H. Tang and Rosalie K. Crouch</i>	
52	Phytochrome: Molecular Mechanisms for Light Signaling in Plants.....	1225
	<i>Jeong-Il Kim, Yun-Jeong Han, and Pill-Soon Song</i>	
53	Blue Light Regulation in Plants and Microorganisms	1237
	<i>Aba Losi and Wolfgang Gärtner</i>	
54	Bioluminescence.....	1265
	<i>Vadim R. Viviani</i>	
55	Artificial Photosynthetic Systems	1289
	<i>Péter Maróti and Massimo Trotta</i>	
56	Fluorescent Proteins: Structural Determinants of Optical Response	1325
	<i>Ranieri Bizzarri and Riccardo Nifosi</i>	
57	Formation and Repair of UV-Induced DNA Damage.....	1349
	<i>Thierry Douki</i>	
58	The Biology of UVA Radiation	1393
	<i>Rex M. Tyrrell and Evelyne Sage</i>	
59	Ultraviolet Radiation and Vitamin D.....	1435
	<i>Lesley E. Rhodes and Ann R. Webb</i>	
60	Endogenous Antioxidant Photoprotection and Its Enhancement in Human Skin	1449
	<i>Maryam Afshar and Antony R. Young</i>	
61	Acute and Chronic Effects of Ultraviolet Radiation, Visible Light, and Infrared.....	1463
	<i>Saroj M. Verma and Gillian M. Murphy</i>	
62	Phototherapy and Photochemotherapy in Dermatology	1475
	<i>Piergiacomo Calzavara-Pinton, Mariachiara Arisi, Bernhard Ortel, and Mariateresa Rossi</i>	
63	Photoimmunology.....	1489
	<i>Vivienne E. Reeve</i>	

64	Photodynamic Therapy	1511

67	Photodynamic Approaches to Water Disinfection.....	1557
	<i>Michela Magaraggia and Giulio Jori</i>	

Preface

The third edition of the *Handbook of Organic Photochemistry and Photobiology* follows a new concept of topical articles and has evolved to a state-of-the-art collection of modern aspects of photochemistry and photobiology.

This compilation of topical reviews comprises very different fields of photochemistry and photobiology. With 67 contributions written by leading experts, this handbook provides leading-edge information on the applications of photochemical and photobiological principles, techniques, and methodologies.

It is a trivial though pivotal fact that natural photosynthesis is the photochemical reaction that integrates photocatalysis and well-balanced steps of energy and electron transfers initiated from electronically excited states. It is the original basis of life on Earth and continues to support us with food, fuel, and oxygen. This process demonstrates that photochemistry can develop into a highly valuable tool for modern organic synthesis. In the history of modern chemistry, there has been a very strong first period of success when numerous light-induced reactions were discovered, modified, and applied to synthetic problems. The organic chemistry community became aware of the reactivity potential of electronic excited states of a molecule. Indeed, photochemistry refers, in many cases, to a multiplication of reactivity options, i.e., in addition to the ground state, electronically excited states show different chemical behavior and often differ so remarkably that they behave as completely new molecules. The modern and powerful techniques of time-resolved spectroscopy approaching new fascinating time domains ("femtochemistry") in the last decades have enabled the photochemistry community to describe a photophysical process in full detail and also to predict photochemical reactivity by application of theoretical methods.

As spectroscopic and analytical tools become more and more sophisticated and theoretical methods develop rapidly, photochemistry and photobiology are merging, and for both areas, interdisciplinary research is essential. Photochemistry is a perfect example of a powerful bridge among chemistry, physics, and biology, and between material science and life science. Chemists worldwide are now aware of the fascinating opportunities that electronically excited molecules present, and this will definitely lead to a new period of exciting developments. Photochemical reactions can be performed at low temperatures, in solid or liquid state or under gas-phase conditions, with spin-selective direct excitation or sensitization, and even multiphoton processes have started to be used in synthetic methods. This handbook provides an overview of these opportunities and tracks the actual developments.

The compilation of this handbook was made possible by the strong cooperation between the editors and the editorial staff at CRC Press, a highly professional and trusting relationship. More importantly, we are deeply indebted to all the contributors for their time and intellectual input that made this compilation possible. We express our sincere thanks to all of them.

Köln, Germany

Michael Oelgemöller

Townsville, Australia

Francesco Ghetti

Pisa, Italy

Editors

Axel G. Griesbeck studied political science and chemistry at the University of Munich, Germany, where he received his doctoral degree in 1984 for work on singlet oxygen. After postdoctoral positions in Würzburg, ETH Zürich, and the Weizmann-Institute in Rehovot, he finished his habilitation in 1991 at the University of Würzburg. Since 1995, he has been a professor of organic chemistry and photochemistry in the Department of Chemistry at the University of Cologne, Cologne, Germany. He was a visiting professor at Wisconsin (Madison, Wisconsin), Tsukuba (Japan), and Tapei (Taiwan) and received the Grammaticakis-Neumann prize in 1997 and the Honda-Fujishima award in 2009. His current research activities are focused on using organic molecules as substrates and as catalysts for photoinduced reactions, either directly excited or generated by energy transfer as well as by electron transfer processes. The reactions are performed in solution phase, in gas phase, or in nanocompartments. Recent applications of these processes are the syntheses of antimalaria-active peroxides by photooxygenation.

Michael Oelgemöller received his diploma from the University of Münster, Germany in 1995 and his PhD from the University of Cologne, Germany in 1999. He was a researcher at the Inoue Photochirogenesis Project in Osaka (1999–2001) and at Bayer CropScience Japan in Yuki (2001–2004). From 2004 to 2008 he held a position as a lecturer in organic and medicinal chemistry at Dublin City University in Ireland. In February 2009, he joined James Cook University in Australia as an associate professor in organic chemistry. In 2000, he received the Kurt-Alder award of the University of Cologne. He was a visiting professor at the University of Pau in France in 2009 and at Osaka Prefecture University in Japan in 2011. His research activities include synthetic organic photochemistry, solar photochemistry, the development of new photochemical synthesis tools, and photochemical water treatment.

Francesco Ghatti graduated with a degree in physics from Pisa University in 1980 and has been a researcher at the Institute of Biophysics (Pisa section) of the Italian National Research Council (CNR) since 1985. His main research topics are photomotile reactions in microorganisms and related primary events of phototransduction and biological effects of environmental ultraviolet radiation on microorganisms and plants. He has served as treasurer of the European Society for Photobiology (1999–present), as president of the Italian Society for Photobiology (2002–2007), and as one of the vice presidents of the International Union for Photobiology (2004–2009). He has also organized several international photobiology congresses, directed NATO advanced study institutes, and chaired numerous symposia.

1.1 Introduction

Tempora mutantur, nos et mutamur in illis—The times change, and we change with them. As progress in physics opened the way to new radiation sources and optical applications, and chemical physics showed the way into micro- and nanoscale technology, awareness grew that photophysical and photochemical processes may lead to new products and more economic manufacturing. At the same time, it was also officially realized that the material and energetic resources of our planet are limited and that the capacity of the planet's ecosystem to digest all kinds of xenobiotic waste is getting to its limits. In this context, different domains of photophysics and photochemistry are receiving more attention and support from both governmental and industrial operators, as they offer the prospect to master key technologies for the development and production of new materials and to lead to new processes that may be qualified as “environmentally friendly” (keyword: green chemistry [1]). This situation fosters research in general but also the technical development of products and processes for a large variety of applications.

It should be recalled that industrial photochemistry comprises a large variety of domains in which compounds are used (i) for their photophysical properties (e.g., fluorescence: optical brighteners [2]; phosphorescence: optical sensors [3]; photochromism [4]: optical sensors and data storage; and energy transfer: photodynamic therapy (PDT sensitizers [5]) or (ii) for their photochemical reactivity (e.g., homolysis: radical initiators [6], surface functionalization [7], and ablation [8]; heterolysis: ionic initiators [6a]; and electron transfer: photocatalysis [9]) to be exploited for the preparation of chemical compounds, materials, and products (e.g., polymers and composite materials of all kinds and shapes). With the same technique, organic compounds, e.g., pollutants in water [10a,b,d,e] and air [10c–e], may also be degraded.

This chapter on “industrial photochemistry” is meant to focus on the domain of preparative photochemistry developed for the industrial production of chemicals and materials of all kinds. In general, the photochemical production of large amounts of chemicals per unit of time demands powerful light sources and corresponding reactors of rather big dimensions and special geometries. Special geometries of irradiation equipments are also needed for the production of, for example, polymer foils and polymer-coated surfaces, small polymer parts, and functionalized nanoparticles. Interdependences

of the many factors that decide on an efficient transfer of radiative to chemical energy were only identified within the last two or three decades. As a consequence, the technical development and exploitation of preparative photochemistry was for a long time disfavored or discarded by prejudices originating from the bad results of too many inadequate and hazardous upscaling efforts [11]. However, after World War II, a number of photochemical processes were successfully developed [12,13], but the work of industrial chemists and engineers involved in these developments was mostly ignored in academic research or kept secret. The publication of a first comprehensive textbook on photochemical technology focusing on the industrial preparative chemistry [14] may mark the renewal of interest in large-scale photochemistry. Considered by many as the reference, it does however not cover all the facets of this vast domain, and a number of reference and textbooks concentrating on some special topics must also be cited [6b,15–17].

Photochemistry was considered for a long time a “playground” for academics doing highly valuable fundamental research but demonstrating little interest in its applicatory potential. For more than 40 years, a quasi-total absence of teaching devoted to the growing interest in photochemical technology left research and development efforts in this domain to a few academic and industrial teams. Industrial chemists, making use of a more or less qualitative knowledge about electronic excited states and multiplicity, and chemical engineers with a solid knowledge in physical chemistry developed large-scale photochemical processes. Their designs are still valid references for new plant constructions [14]. Some very important technical developments, such as digital photography [18], micro- and nanoscale lithography [19], ablation and etching for the production of all kinds of electronic devices [8], optical sensors [3], photoelectrochemical devices [20], and light emitting diodes (LEDs) [21], were mostly developed outside the mainstreams of research in academia. Most recent developments in the domains of renewable energies, medicine (e.g., diagnostic devices, therapeutic equipment), communications, etc., are for a large part based on the use of photophysical and photochemical processes, and the present exponentially growing need of specialized scientists and engineers is finally answered with the most recent implementation of a number of curricula in the domain of photonics at well-known academic institutions.

Preparative photochemistry is mostly applied by chemical companies that produce intermediate and/or fine chemicals (e.g., pharmaceutical, agrochemical, food processing, and fragrance industries) and by companies producing basic or final products, for example, food, electronic, automotive, furniture, building, and packaging industries. It is impossible to establish a complete list of products that are prepared on a large scale by photochemical processes, and nondisclosure agreements prohibit to relate products with industries involved. However, given the large diversity of products, a nonexhaustive list of companies may be cited for their interest in photochemical synthesis without divulging details of their activities: Astra Zeneca, Balmer Lawrie, BASF, Bayer, Bristol Myers Squibb, Clariant, CSS Almac, Leo Pharmaceutical Products, Monsanto, Rhishiroop, Sanofi-Aventis, Sasol, Solvay, Symrise, Tata Chemical, and Toray. [Table 1.1](#) summarizes the most important photochemical reactions and classes of products prepared or the processes relying on the first.

In the domain of photochemical environmental techniques, Areva, Suez, and Véolia are certainly among those mostly known in Europe.

The importance of industrial scale preparative photochemistry may be demonstrated by the electrical power installed for the radiation sources of the photochemical reactors. [Table 1.2](#) shows those data for the preparative photochemical equipment installed and maintained in western Europe as far as the authors contributed to its installation.

Published information about corresponding installations in eastern Europe and Russia, but also on the American continent is not available to the authors. Industries in Korea and Japan make use of photochemical reactions since many decades, and there are no signs that these activities would decrease. In addition, new demands from China and India reflect a rapidly growing interest, and for Asia, the total electrical power installed in preparative photochemical equipment may be largely underestimated. Based on the information available to the authors, 30 MW of worldwide installed electrical power in

TABLE 1.1 Most Important Photochemical Reactions Used in Industrial Photochemistry

Photochemical Reaction	Products and Processes
Chlorination	Acylchlorides Alkylchlorides Arylchlorides (Poly)Chlorinated polymers Chlorination of organic surfaces
Electrocyclic reactions	Vitamin D derivatives
Isomerization	Vitamin A precursors and derivatives Stilbene derivatives
Nitrosylation	Lactams
Oxychlorination	Oxidative functionalization of polymers Oxidative degradation of organic pollutants
Oxidation	Oxidative degradation of organic pollutants Alkylchlorides Activation of inorganic surfaces Functionalization of organic surfaces
Catalyzed oxidation	Treatment of polluted air
Initiated oxidation	Treatment of waste water
Sensitized oxidation	Terpenoids O-Heterocyclic compounds
Cationic polymerization	Vinyl-type (pre)polymers Surface coating and polymer materials
Radical polymerization	Vinyl-type (pre)polymers UV curing (surface coating and printing)
Sulfochlorination	Alkylsulfonylchlorides
Sulfoxidation	Alkylsulfonic acids

TABLE 1.2 Preparative Photochemical Activities in Western Europe Represented by the Electrical Power of the Radiation Sources Installed^a

Location	Electrical Power of Radiation Sources Installed (kW)
France	1800
The Netherlands	1250
Belgium	190
Germany	2700
Italy	650
Others	160
Total western Europe	6750

preparative photochemical equipment seem realistic. Observing over the last two decades a slightly decreasing activity in western Europe, these estimates reflect the delocalization of modern production facilities to emerging countries, whereas small units for highly specialized applications remain at the traditional centers of research and development. This trend will most probably be amplified within the European Union by new regulations that restrict the activity of the chemical industries with arguments

propagating lowest risks for the environment of its inhabitants and improved levels of health and life expectancy. Saving on costs of transportation and environmental regulations and taking advantage of cheap labor on all levels, photochemical techniques aiming at new products by the transformation of materials will be developed in regions where raw materials are available and intermediate chemicals are already prepared.

It must be emphasized that a combination of the data shown in Tables 1.1 and 1.2 and of other estimates mentioned reveal that the production of highly priced fine chemicals (e.g., fragrances, pharmaceutically active compounds) does not represent the major fraction of installed electrical power, and this fact invalidates the old prejudice that preparative photochemistry may only be applied for the production of compounds and materials of high added value.

Using very similar equipment, photochemical environmental techniques [10] should also be mentioned in this chapter. Several multinational companies use photochemical processes for the abiotic treatment of waste water, and facilities with up to 200kW of installed electrical power are known. Organic pollutants dissolved or suspended in water are partially or entirely oxidized by using H_2O_2 - or $\text{O}_3/\text{H}_2\text{O}_2$ -photolysis or the photochemically enhanced Fenton reaction [23], in the presence or absence of an additional enhancement by Fe(III) oxalate photolysis [23b]. TiO_2 -photocatalyzed oxidative degradation of organics in condensed aqueous phase is a frequently cited topic of research, but there is so far no information available that would confirm its successful large-scale application.

Vacuum-ultraviolet (VUV) photolysis and/or TiO_2 photocatalysis are most efficient for the *treatment of polluted air* [10c–e], and reactor modules based on the latter process are emerging rapidly, as TiO_2 -functionalized surfaces (glass, quartz, zeolites, etc.) become commercially available. Different designs of reactor modules are offered by mostly newly founded companies, and some time will be needed to see this promising market structured.

UV-C irradiation for water disinfection [10a,b,24] is a still growing market, and the electrical power of the corresponding photochemical equipment reached certainly more than 100 MW. The domain of water disinfection is a large-scale photochemical application and is mentioned here, because equipment similar to that needed for preparative photochemistry is used. Since a few years, dye-sensitized singlet oxygen production is proposed as an alternative means of water disinfection. Such a process might show an economic advantage in cases where water can be recirculated and sunlight could be used for electronic excitation (e.g., fish ponds, cooling circuits) [24b,c].

1.2 State of the Art in Industrial Photochemistry

Due to many adverse factors, large-scale preparative photochemistry for the syntheses of chemicals did not show signs of progression until recently. The industrial use of photochemistry focused primarily on the evolution of microelectronics (Figure 1.1) and on large-scale surface treatment [17] (Figure 1.2) as spin-offs of new inventions and fast developments in the domain of polymer photochemistry [6,19]. Until the mid-1980s, silver halogenide photography found its peak in a last refined development of large dimensioned and brilliantly colored pictures [25] as well as in the instant picture development [26], but industrial laboratories were turning already toward digital alternatives [18].

1.2.1 Radiation Sources

Preparative photochemistry was more or less limited to the use of low and medium-pressure mercury and sodium arcs, and some processes were developed with tungsten lamps and fluorescent tubes [14]. Usually, this restricted choice did not allow an optimal selection of the spectral domain of electronic excitation, and mostly liquid filters were used to limit irradiation in particular toward higher photonic energies [14,28]. Glass filters [29] were and are not always available at affordable costs for pilot

or production scale equipment. With the implementation of a variety of doped medium-pressure mercury arcs, the relatively widespread spectral distribution of the mercury lines could be concentrated to given spectral domains (Figure 1.3 [29]) with the corresponding benefits in energy costs and restricted side reactions.

In the mid-1980s, the first excimer radiation sources became available [30], and it was expected that this new class of radiation source would boost the technical applications of preparative photochemistry for three reasons: (i) the quasimonochromatic emissions of these sources would lead to more specific electronic excitations and therefore to higher yields of pure products [31], (ii) “lamps” without electrodes fixed to their envelope (“electrode-free lamps”) would allow to adapt their forms and dimensions to those of the photochemical reactors and therefore to the given characteristics of the photochemical processes [32], and (iii) excimer “lamps” can be used in a pulsed mode that may induce higher yields and better product qualities [33]. Excimers were already generated earlier by microwave-driven excitation of

the emitting gas phase, a technique that might show advantages due to a rate-enhancing effect attributed to a simultaneous microwave excitation of the reaction system [34]. However, such radiation sources lose the advantage of “electrode-free lamps,” since the microwave conduction between generator and “lamp” restricts the reactor design possibilities.

In retrospect, excimer radiation sources could not substitute the conventional arcs, although some very interesting applications in preparative photochemistry became known [35]. Main reasons include (i) the lack of a product line of commercially available excimer radiation sources of different electrical power reaching from laboratory to pilot scale, (ii) the spectral domain of useful excimer emissions, which is restricted to the VUV, UV-C to UV-B spectral regions, and (iii) the very high costs for “lamp” and corresponding power supply. Nevertheless, XeCl excimer (λ_{em} : 308 nm) could successfully replace the conventional medium-pressure mercury arc in printing processes (UV, curing ink drying [36]) due to the lower operational temperature of the former.

The Xe₂ excimer radiation source (λ_{em} : 172 nm) must be mentioned for its impact on vacuum-ultraviolet (VUV) photochemistry, a domain rarely mentioned outside fundamental research in spectroscopy and radiation chemistry. In fact, the development of these radiation sources brought a revival to water homolysis, reported since long with photonic energies higher than 6.2 eV [37], and therefore to environmental techniques [10b–d]. Xe₂ excimer emission might be produced with efficiencies as high as 40% of the input electrical power [38] and was used successfully in processes of surface activation and functionalization (Figure 1.4) of films [39] and aerosols [7] due to the photochemical reactivity of C–C bonds.

FIGURE 1.5 Pilot installation dedicated for waste water treatment with an “amalgam lamp.” (Reactor manufactured by UV-Consulting Peschl and located at the Université Paul Sabatier, Toulouse, France. With permission.)

In condensed aqueous phases, the absorption cross section of H_2O is quite high at $\lambda_{\text{exc}} = 172 \text{ nm}$, and limitations in upscaling [40] can be avoided with the use of O_3 -producing doped low-pressure mercury arcs (“amalgam lamps”) with main lines of emission at 185 and 254 nm. The two lines exhibit radiation powers of <10% and approximately 40%, respectively, of the electrical power [29] (Figure 1.5). These arcs became very rapidly a standard in environmental techniques and water disinfection. All “lamps” emitting in the VUV spectral region may be mounted in installations, for example, for the treatment of off-gases originating from chemical production units, biological water treatment stations, large kitchen units (Figure 1.6, e.g., fast food providers), and spray-dyeing workshops. VUV-driven TiO_2 -photocatalytic processes might show higher efficiencies than those installed with UV-C and/or UV-A and UV-B excitation [41]. Care must be taken that O_3 is eliminated before treated off-gases are leaving such installations.

The introduction of LEDs provides an even larger choice of radiation sources. LEDs combine the advantage of a quasi-monochromatic emission, at present in the UV-A and VIS spectral domain, with those of long lifetime and the possibility of pulsed operation. However, LEDs do not exhibit design advantages of “electrodeless lamps,” but may represent an optimal choice, when used in more or less large arrays in equipment for surface reactions (Figure 1.7) or in all kinds of immersion-type reactors. LEDs are also the perfect choice in combination with mini- or microreactors.

Solar irradiation is, of course, limited to photochemical processes with electronic excitations in the UV-A and VIS regions. Such processes should also be thermally insensitive. Large variations in incident photon fluxes, in particular day/night cycles, might be compensated by the installation of a series of reactors by which excitation by solar and artificial radiation can be combined.

1.2.2 Reactor Design

Mini- and microreactors might be used more frequently in future projects of preparative photochemistry, when chemicals of up to a few 100 kg/year are to be produced. However, immersion-type reactors of all kinds are still a standard in large-scale preparative photochemistry as well as for photochemical environmental techniques. They range from large volume multilamp installations, built in most cases for heterogeneous gas/liquid reaction mixtures (e.g., photosulfoxidations) and showing surprisingly high efficiencies, to one-lamp tubular reactors. Earlier, most production-scale photochemical processes were made in reactors that contained the volume of an entire batch. Experience taught, however, that semibatch installations, where the reaction medium circulates between a large central reservoir and a number of smaller reactors, present a number of mostly technical advantages [14]. Such installations ensure a rate of production largely independent of maintenance and repair and flexible to the needs of the market. They also provide better conditions for the optimization of flux (turbulence) and gas saturation. In addition, further development to a continuous process mode is made easier since the performance of one photochemical reactor in use is already known, and a parallel reactor configuration may be changed into an “in series” configuration without great difficulties. The efficiency of an immersion-type reactor depends primarily on the ratio between the irradiated and the reactor volumes, and, generally, ratios of 1/1.2–1/1.5 should be chosen. The irradiated volume may be evaluated knowing the absorbance of the photochemically reactive substrate, that is, its concentration and molar absorption coefficient at a given wavelength of excitation, and the dimensions of the radiation source. As the length or height of the reactor is given by the length of the radiation source, the volume of the reactor may be varied by changing the diameter of the cooling or protection tube representing the inner wall of the reactor volume (Figure 1.8). Several academic research groups focused their interest on model calculations of shape and dimension of an irradiated volume that depend on the dimensions and the spectral and operational characteristics of the radiation source as well as on the spectral absorption characteristics and the concentrations of the components of the reaction system [42,43]. Beside volume considerations, incident photon flux density, optimized flux of the reaction system, temperature control, gas saturation, and the probability of secondary reactions (e.g., filming) are usually the main factors affecting reactor design. In most cases, design work is made empirically, although some of the parameters might be calculated or pictured under assumed constraints with the use of specialized software.

As already mentioned, photochemical mini- and microreactors are a recent topic in industrial preparative photochemistry. Photochemical minireactors and irradiation equipment are already commercially available. The example of a production-scale application shown in Figure 1.9 uses thin-film minireactors positioned into the parallel beam of incident photons.

FIGURE 1.9 (See color insert.) Photochemical mini-(thin-film) reactors of a production unit installed in a ventilated closet. (Picture shown with the kind permission of Heraeus, owner of IP rights of the pictured installation.)

Quite a number of academic and industrial research groups work at the implementation of photochemical microreactors. Microreactors represent at present the ultimate solution for problems of mass and photonic energy transfers encountered in larger reactor units. The material of the reactor body, its combination with a glass or quartz window, channel design, and dimensions depend strongly on the photochemical process to be developed, and some specialized equipment builders propose interesting solutions, but so far, no application became known.

As the photochemical reactor design depends on the reaction system to be treated, new challenges arise with the use of (micro)heterogeneous systems. Special designs are also needed for photochemical bioreactors [44], and new developments make use of combinations of differently emitting LEDs tuned on maximum growth of biomass.

Positive reaction geometries, where “lamps” are positioned outside and their emission focalized on a reactor tube [14], are no longer used for water disinfection but still represent simple and cheap solutions for chain reactions exhibiting high quantum yields and exothermicity (e.g., photochlorination), as they are now exploited in developing and emerging countries.

1.2.3 Upscaling/Downscaling

Upscaling means to change all process parameters determined for an optimized laboratory-scale reaction to achieve production of a previously fixed mass of product per unit of time in an installation adapted accordingly. In the course of developing a given photochemical process, care must be taken that only equipment is used that may be upscaled without technical problems. Such problems are primarily linked to the availability of large radiation sources and filters. For laboratory-scale photochemical processes, batch or semibatch equipment is most frequently chosen, but semibatch or continuous modes are definitely favored for technically developed processes. Such a change calls in most cases for an intermediate pilot phase in which process parameters are again optimized using a pilot reactor of the same or at least similar design than that foreseen for the reactor(s) of the production unit. Development on a laboratory scale concerns primarily the operational mode, the type of radiation source, the design of the photochemical reactor for a given class of reaction, and the absorption cross section of the substrate(s) within the actinic important spectral range, and incident photon flux density and residence time are the primary parameters to be optimized. Based on the results of optimized laboratory experiments, the electrical power needed for the radiation sources to be used to fabricate a previously fixed mass of product per unit of time can be evaluated by linear extrapolation. Radiation density, size, commercial availability, and replacement costs on one side and economic considerations (space to be attributed, investment including accessory equipment, operational period of reactor(s), costs of maintenance, costs of safety measures, availability and costs of specialized working force, etc.) on the other are the top priorities to decide on the power of the radiation sources and the number of reactors to be installed. As the rate of the photochemical reaction depends primarily on the rate of absorbed photons, upscaling is much simplified, if the absorbed (spectral) photon flux density [45] is kept constant within a limit of $\pm 10\%$. For that purpose, the absorption conditions are kept constant, and radiation sources of increasing electrical power but similar incident photon flux density are used. Some brands of radiation sources are now commercially available in series that ensure similar radiation densities over a large range of electrical power.

Quantitative analyses of a number of pilot and production-scale reactors installed over a period of some 20 years show that practically all installations operate at the upper limit of radiation density (“over-irradiation”), hence producing high concentrations of excited states and reactive intermediates that are difficult to be trapped quantitatively within their lifetimes. Deviations from optimal process conditions (e.g., concentrations, flux) may therefore favor different reaction channels leading to secondary products and reactor filming. In sensitized processes, where a chemically inert sensitizer is excited and highly reactive intermediates should be quantitatively trapped, high radiation densities may simply lead to a strong decrease of substrate concentration within a fraction of the time of residence and, therefore, to a waste of energy. While the radiation density in the actinic important spectral region of a given process is primarily determined by the power and the dimensions of a given type of radiation source, fine-tuning is always possible by varying the diameter of the inner wall of the reactor. The problem of “over-irradiation” may, however, also be solved by pulsed excitation of suitable radiation sources. The incident photon energy per time of residence may then be optimized by varying the frequency of the exciting flashes.

As already mentioned earlier, the flow characteristics of the reaction system through the photochemical installation are a very important process parameter. Low fluxes may result in a depletion of substrate(s) at times inferior of the time of residence, and bimolecular reactions require turbulent flow conditions to ensure acceptable efficiencies. In falling film reactors [14], the dimension of the

FIGURE 1.10 Microreactor module made of silicon. (Picture taken at the Lehrstuhl für Umweltmesstechnik, University Karlsruhe, Germany. Reactor module developed by IMTEC, University of Freiburg, Germany. With permission.)

photochemical reactor and the flux of the reaction medium determine the volume and therefore the thickness of the falling film. Since this thickness can only be varied within a small range, efficient trapping of reactive intermediates depend on the turbulence and enhanced gas absorption due to the tumbling of the falling film, but may also be affected by the incident radiation density and, where necessary, by increased gas pressures.

For smaller production levels (up to a few 100 kg/year), upscaling may in fact consist of downscaling and multiplying reactor units operating in parallel. On first sight, such installations appear complicated, implying large numbers of pumps, complex piping, and gas supplies and may therefore also call for additional means as far as safety is involved. Total costs of investment and maintenance seem higher, but there are a number of economical and technical advantages to consider. Such installations need less space and the rate of production may be more rapidly adapted to the needs of the market. The combination of mini- or microreactors with the appropriate radiation source provides optimum conditions of electronic excitation, and gas dissolution/saturation and turbulence reach maximum levels in microchannels (Figure 1.10), hence ensuring best results (efficiency, quality of product) for processes in which electronically excited states or highly reactive intermediates have to be trapped by photochemically inactive reactants. Once a process is optimized on a mini- or microreactor scale, upscaling is a simple operation of multiplication. For safety reasons, processes might require confined spaces with special atmospheric treatment, and arrays of mini- or microreactors can be rapidly installed in such an environment.

Recently, a similar principle was adapted for larger scale photochemical reactors by conceiving a laboratory-scale tubular reactor module that may be simply multiplied in its length depending on the dimensions of the radiation source [46]. The optimized performance of the laboratory-scale module being determined for a given process, the elongated pilot or production reactor is rapidly optimized by adapting the reactant concentrations. The new design found already first applications in photochemically advanced oxidation processes.

1.3 Large-Scale Preparative Photochemistry and Means of Safety

In addition to the measures of safety imposed by the handling of chemical compounds in a given process, the use of photochemical equipment demands a special means of safety that concern radiation, electrical incidents, glass or quartz tube failures, hotspot-initiated explosions, and/or fire and temperature control.

1.3.1 Radiation

The effects of radiation may be roughly divided into those damaging the skin and those damaging the eye. In addition, polymer composite materials that might be used within the radiation field will be photolyzed and damaged, and resulting leaks of gases or liquids must be avoided by periodic inspection of such parts.

Photodermatology differentiates three spectral domains generating different degrees of skin irritation and damage: UV-C (200–280 nm), UV-B (280–320 nm), and UV-A (320–380 nm) [14]. Using radiation sources emitting these kinds of radiation, danger is imminent, when these “lamps” are used without being positioned inside adequate protection tubes or reactor vessels. Immersion, cooling tube, and protection tubes (Figure 1.8) that are made of synthetic or natural quartz do not provide protection, but those made of borosilicate protect at least against radiation at wavelengths <320 nm. The same holds for reactor vessels that are made of borosilicate. UV radiation transmitted through a reactor filled with reaction medium is mostly negligible (depending on the absorption of the medium), and VIS radiation (light, wavelengths >380 nm) is at the present state of knowledge of no concern for the skin. UV radiation at wavelengths <200 nm is absorbed by molecular oxygen contained in air, hence its penetration through air depends on the wavelength-dependent absorption cross section of molecular oxygen. Safety rules for VUV radiation sources should be the same as those imposed for UV-C sources.

It must be emphasized that the most sensitive organ exposed to radiation is the eye. Wanting to see what is happening, it is usually forgotten that damage to the eye may be fast and in most cases irreversible. Eye protection is not only required when dealing with UV radiation, exposure to intense VIS radiation may lead to mostly reversible blindness, but at higher doses to retina damage. Therefore, protection glasses should be worn when performing all kinds of photochemical experiments, and dark protection glasses when radiation sources are used that emit at wavelengths >320 nm.

Protection against radiation is already necessary for laboratory-scale experiments and is mostly accomplished with shields made of black tissue or aluminum foil. On large-scale reactors (enameled) stainless steel equipment provides best protection but cannot always be used, because reaction systems might be sensitive to metal ions contained in and leached from the reactor wall. Where reactors are made of borosilicate, protection against VIS radiation may consist of shields or curtains preferably made of blackened aluminum or aluminum foil.

1.3.2 Electrical Incidents

With the exception of tungsten lamps, fluorescence tubes, and some halogen lamps, radiation sources must be operated with a power supply. The power supply is necessary to ignite the arc through the gas phase containing the emitting atoms or clusters of atoms (e.g., mercury, sodium) and to maintain a constant operating voltage. Igniting voltage peaks may vary between 2000 and 6000 V, and, for example, low- and medium-pressure Hg arcs are driven between 30 and 100 and between 100 and 3500 V, respectively. From these data result considerable currents and care should be taken that all electrical connections (plugs and cables) are protected. Commercially available lamps are equipped with special plugs to avoid false connections. Power supplies are usually located outside the range of potentially spilled areas, and when handling flammable solvents or when working in an environment that must be kept explosion proof, special ventilated rooms are an advantage or may even be required.

Particular care for sufficient insulation must be taken when operating excimer radiation sources. These sources are driven with potentials of 3000–8000 V at frequencies in the range of 80–200 kHz. Under these conditions, insufficient or damaged insulation may cause the propagation of high-frequency potentials over the entire surface of an installation. Clamps, usually provided with protection sheets made of cork or plastic, do not provide sufficient insulation, and entire mounting racks may show St. Elmo's fire. Since damages on plugs or cables might not be readily detected, connections of all the different parts of an installation to the ground are certainly providing best levels of safety. Commercially available combinations of power supply, radiation source, and connections are equipped to avoid electromagnetic fields even at close

distance from the installation. This is not necessarily the case for self-made or assembled equipment, and at higher powers, means of protection (e.g., Faraday cages) are recommended.

1.3.3 Glass or Quartz Tube Failures

The probability that immersion, cooling, and/or protection tubes (Figure 1.8) made of quartz and/or borosilicate would break is very small, as long as fundamental safety rules are maintained. Quartz is more resistant to thermal shocks than borosilicate and is usually chosen for the most inner (immersion) tube of the well into which the radiation source is mounted. In accord with the required conditions of irradiation, temperature, and pressure, the outer tubes of the well might or must be made of borosilicate. Filter glasses (e.g., mixtures of quartz and borosilicate, colored borosilicates) might be mechanically fragile, and their use as material of construction has to be tested. Diameter and wall thickness of these tubes depend on the radiation source chosen (type, dimension), the incident photon flux density to be implemented, the flux of the cooling medium (if any), and the pressure required for a given process. Well tubing should be periodically inspected for cracks and cleaned from all kinds of stain developing on the surface exposed to the reaction and to the cooling medium as well as inside the cavity of the radiation source.

Most of the very large photochemical production units are made of stainless steel. In most cases, this is a matter of mechanical and thermal stability. Over the last decades, equipments made of borosilicate gained in importance, in particular for smaller reactors (≤ 20 kW), because the material exhibits excellent chemical inertness, and glass reactors require much smaller investments. However, it cannot be denied that mechanical and thermal shocks are the biggest threat to such installations. In development, glass reactors are highly appreciated, because they provide optimal conditions to observe the effect of most important factors of process optimization, such as fluid dynamics, gas introduction, and distribution as well as field and absorption of radiation.

1.3.4 Hotspot-Initiated Explosions and/or Fire

All radiation sources produce heat. While heat production by fluorescence tubes might be negligible, low-pressure arcs and excimer radiation sources may reach maximum surface temperatures of 120°C–150°C. The mostly used medium-pressure mercury arcs require an optimal operational surface temperature of 850°C; consequently, the temperature of the electrodes may reach 1350°C. Gaseous organic compounds entering the lamp cavities may be ignited, hence initiating explosion and fire within the space of a production unit. This danger can be averted by introducing an inert and UV-transparent gas into and to the bottom of the cavity and by maintaining a slight overpressure within the cavity that prevents other gases from penetrating into the space, where the hotspot is located. The absence of molecular oxygen from the cavity also diminishes considerably the rate of electrode oxidation at elevated temperatures, and maintaining a nitrogen atmosphere within the cavity is affecting favorably the lifetime of the radiation source and therefore one of the most important factors of maintenance: lamp replacement. Depending on the type of radiation source, the introduction of nitrogen into its cavity might be mandatory in order to prevent ozone generation. Usually, a flow control system regulating the inert gas flow is linked to the controls of the power supply of the radiation source.

1.3.5 Temperature Control

Depending on (i) the radiation source to be used, (ii) the photochemical process, and (iii) the thermodynamics of the process, cooling circuits must be installed. Water is usually taken as a cooling liquid circulating through an outer layer of the well limited by the immersion and the cooling tubes (Figure 1.8). But other cooling liquids may be used, as long as they are transparent in the spectral region of interest, photochemically stable, and complying with all safety regulations. For reasons of environmental protection and increasing costs of clean water, closed cooling circuits with tap water may be installed. Pure deionized

water should not be used, because it will corrode metal and borosilicate surfaces. Water cooling through the well of a radiation source serves two purposes: (i) maintaining an optimal operational temperature of the radiation source and (ii) absorbing the infrared radiation emitted by the radiation source, hence contributing to an efficient thermoregulation of the reaction system. Liquid filter systems that restrict the emitted polychromatic radiation to the spectral region of interest may be used as well. It is most important that the flow control system of the cooling circuit can interrupt the irradiation in case of failure.

Water absorbs VUV radiation and corresponding cooling circuits cannot be installed in the outer layers of a well protecting a VUV-emitting radiation. Some radiation sources may comprise an internal cooling circuit using the cavity of the potential-bearing electrode. In these cases, the use and periodic control of distilled (deionized) water is mandatory. Commercially available radiation sources may not require additional cooling or comprise an internal cooling circuit and corresponding controls.

1.3.6 ATEX or NEC Certification

Integral safety measures may be installed with ATEX- (ATmosphere EXplosible) or NEC-certified equipment. The EU regulation 94/9/EG (ATEX 100a) and the US regulations NEC 500/505 classify the requirements imposed on the equipment and on the safety measures necessary in order to ensure safe operational conditions in potentially hazardous areas. Consequently, only ATEX- or NEC-certified equipment can be installed and used in photochemical processes on an industrial scale, where organic solvents are to be used. ATEX-certified irradiation equipment from 2 to 40 kW is commercially available, and large-scale photochemical processes can nevertheless be realized.

ATEX certification is based on a risk analysis and on the corresponding tests of all parts in interaction with the irradiation equipment: radiation source, metal parts, quartz or glass tubing (wells) as well as electric supply and electronic controls. Besides measures to prevent explosion of gases in hotspot zones, special attention is given to the safety of the irradiation system. Radiation sources might implode provoking short circuits as well as cracks and breakage of the surrounding quartz or glass tubes. Leaks in the well might lead to an immersion of the lamp cavity by the cooling liquid and/or the reaction system, but a destruction of the well should never be the origin of a fire under these safety conditions. Certified radiation sources are sold with a minimum lifetime guarantee and a tested breaking behavior reducing considerably the threat of damaging the surrounding quartz or glass tubes. Transparent materials used for the construction of the well must be tested (Figure 1.11) to ensure their stability in case (i) of fast rising

FIGURE 1.11 Setup of tests for a photochemical reactor comprising a 40 kW medium-pressure mercury arc. (Picture from UV-Consulting Peschl. With permission.)

FIGURE 1.12 Electric and electronic control systems for the installation of 5×20 kW medium-pressure mercury arcs. (Picture from UV-Consulting Peschl. With permission.)

temperatures within the operational limits of the radiation equipment, (ii) of mechanical stress (impact of fragments, temperature-dependent dimension variations), and (iii) of sudden drops of temperature (e.g., in case of emergency cooling). Special tests are required for processes under pressure. The loss of pressure and/or flow of the cooling medium and the increase of temperature must be permanently controlled for a given irradiation system.

The risk analysis as well as all tests results must be documented and serve as a basis for the operating manual. Finally, the classification of the irradiation system must correspond to the requirements imposed by a given chemical process. ATEX-certified electrics and electronics (Figure 1.12) control the safe operation of radiation sources autonomously, through permanent voltage measurements, ground fault monitoring, and links between the flow controls of inert gas and water and the safety switches of the power supply.

1.4 Summary

This chapter focuses on and describes the present state of the art of large-scale preparative photochemistry and is meant to be a brief update of the presentations given in a number of earlier textbooks and reviews. New developments of radiation sources (excimer and LED) and the introduction of photochemical mini- and microreactors confirm the actual interest and open new domains of industrial applications. Safety requirements and respective costs are most often critical factors in deciding for or against the implementation of a photochemical process, and corresponding frequently evoked problems are discussed.

2.1 Vacuum-Ultraviolet and UV Excilamps in Photoscience

During the past two decades, the development of modern excilamps initiated an enormous number of laboratory investigations in photochemistry and related fields, and it also led to various industrial applications. The interdisciplinary aspects of these developments were summarized in several recent reviews [1–6]. The current presentation highlights tendencies and developments of future significance in this area of research and development.

The organization of this contribution follows the sequence of keywords presented in [Table 2.1](#): initially, some industrial and medical applications and the development of mercury-free artificial lighting systems will be mentioned. Thereafter, photochemical processes of surface modification and surface cleaning that are of utmost industrial importance in material sciences and nanotechnology will be presented. Subsequently, applications of excilamps in analytical instrumentation and the development of novel actinometric procedures for the measurement of the photon flux q_p of excilamps will be discussed. Also, the use of excilamps in synthetic photochemistry will be briefly described. Another part of this review will deal with destructive photochemical processes that are under active investigation, for example, surface disinfection, vacuum ultraviolet (VUV) or UV disinfection of aqueous systems, and advanced oxidation processes (AOPs) for water and air treatment. All processes mentioned in [Table 2.1](#) are based on photo-induced changes of chemical entities.

The reason for the worldwide interest in the use of this lamp generation is related directly to its extraordinary characteristics: excilamps are mercury-free gas-discharge sources of noncoherent VUV or UV radiation with high radiant power of up to 700 W cm^{-2} [7]. The spontaneous emission of radiation is based on the formation of short-lived excimers or exciplexes, which can be either produced by dielectric barrier discharges (DBDs, silent discharges) [8,9], by capacitive discharges (CDs) [10], or by other techniques [11] including corona discharges [12,13]. Excilamps are nonlaser sources of radiation. In contrast to lasers they

provide almost monochromatic (narrow-band) and noncoherent radiation with a full width at half maximum (FWHM) of less than 15 nm. The wavelength of the emission maximum depends on the nature of the gas-filling components (Table 2.2). Thus, excilamps cover a broad range of radiant energy (Table 2.2) that can be used for selective initiation of photochemical reactions and processes.

The acronym “excilamp” describes two kinds of noncoherent VUV or UV sources. It was first introduced by Tarasenko [15]. An excimer or exciplex is an electronically excited dimer (e.g., a xenon excimer, Xe₂^{*}) or an electronically excited complex (e.g., a krypton chloride exciplex, KrCl^{*}), respectively [16]. These electronically excited molecules are short-lived species that decompose within nanoseconds with the formation of the electronic ground states of the participating atoms accompanied by emission of radiation. Some representative emission spectra of excilamps are presented in Figure 2.1.

Excilamps are so-called cold lamps that exhibit almost no infrared (IR) emission. Thus, they are ideally suited for low-temperature photoprocessing of temperature-sensitive materials. The variable power adjustment enables instant start at full radiation output. In addition, the so-called electrodeless configuration guarantees a long lifetime of several thousand hours of operation [17,18]. Possible mechanisms for the limitation of the lifetime of CD-driven exciplex lamps were discussed by Sosnin et al. [18].

Interestingly, excilamps exhibit an unprecedented variation in geometrical design of the lamp's body. Due to the “electrodeless” configuration (Figure 2.2) of the setup, the lamp body of excilamps may be designed as tubular structures radiating outward or inward. In this context, “electrodeless” means that the hot and the ground electrode are not in contact with the plasma producing gas or gas mixture. Additionally, special geometries, flat panels [19–23] or excilamps with a large emitting surface [24,25], and windowless or open systems are possible [9,26–30] (Figure 2.3). This enormous variability of geometrical options of

(Photo courtesy of T. Oppenländer, Hochschule Furtwangen University.)

excilamp design enables engineers for the first time in photochemical engineering to adapt the geometry of the lamp to the reactor system or to the photochemical reaction conditions [31]. Furthermore, an upscaling [32,33] and the miniaturization [34] of excilamps are easily possible.

A typical flow-through photoreactor configuration for the irradiation of aqueous or gaseous media [35–38] is shown in Figure 2.4. In this example, the excilamp is used with its radiation directed inward by applying VUV/UV-reflecting aluminum as the outer electrode.

The tubular excilamp configuration allows the variation of inner electrodes and inserts. For example, the inner electrode may consist of a spiral metal wire or of a metallic static mixer (Figure 2.5A) [39]. Furthermore, inserts like semipermeable ceramics can be axially mounted within the flow of the medium to introduce gases locally into the irradiation zone (Figure 2.5B) [40].

The electrical behavior of excilamps is still under active investigation [41] with the objective to enhance the radiant efficiency (η), i.e., the ratio of radiant energy Q_λ to the input of electrical energy W_{el}^{in} , $\eta = Q_\lambda / W_{el}^{in}$. For example, Merbahi et al. [41] confirmed a VUV efficiency of a single xenon microdischarge of about 55%–60%, and Shiga et al. [19] calculated that almost 80% of the electron energy is deposited in the electronic excitation of Xe. Under their experimental conditions, most of this energy is converted to VUV radiation. Salvermoser and Murnick [13] reported a conversion efficiency of their Xe_2^* excilamp of greater than 50% using a corona discharge in xenon gas. However, typical commercial excilamps exhibit radiant efficiencies between 5% and 40% [1]. The most efficient Xe_2^* excilamp that is currently available on the market is the Xeradex* VUV excimer lamp system

with a stated radiant efficiency (η) of 40% at an electrical input power of 20, 50, or 100 W. [Figure 2.6](#) shows a photo of a DBD-driven tubular XeCl^* excilamp that demonstrates typical discharge phenomena constituted either of thin current filaments (microdischarges) or of homogeneous discharges. The complex physical phenomena that trigger these different discharge modes were discussed explicitly by Kogelschatz [42].

2.2 Industrial Applications

Low- and medium-pressure mercury lamps are widely used UV sources. They are extensively applied in various industrial areas, for example, for the disinfection of water, air, and surfaces; for UV curing of lacquers, resins, adhesives, and paints; for photochemically initiated advanced oxidation processes (AOPs) for water (e.g., [43]) and air purification and detoxification; and for therapeutic treatment of skin diseases, for example, phototherapy of psoriasis. Especially, the lighting industry uses low-pressure mercury gas-discharge tubes for illumination purposes. They contain additional luminescent material (so called phosphors [44,45]) for the conversion of the 254 nm radiation to visible light, for example, modern fluorescent energy-saving lamps. However, mercury is a toxic element and therefore the disposal of fluorescent lamps is hazardous and dangerous for the environment and human health.* Fortunately, the development of mercury-free excilamps led to new developments and prospects in these fields of R&D. Further, it opened up novel possibilities of applications in emerging scientific areas like nanotechnology, photolithography, photochemical vapor deposition (photo-CVD), modification of surface properties, or contact-free surface cleaning.

2.2.1 Plasma Displays and Artificial Lighting

During the past decade, the sales of AC plasma displays (PDPs) emerged as a multibillion market [46–48]. PDPs are used as large flat television screens, which also can generate three-dimensional (3D) images [49] by the field-sequential technique. They utilize the radiation emission of noble gas excimers (usually a Xe/Ne mixture) at high partial pressure that are produced in microstructured stripe barrier ribs [48] by DBDs. The VUV radiation excites red, green, and blue luminescent phosphors that are located within the ribs and that convert the VUV radiation to visible light via photophysical mechanisms. Conventional PDPs use $\text{Zn}_2\text{SiO}_4\text{:Mn}^{2+}$ or $\text{YBO}_3\text{:Tb}^{3+}$, $(\text{Y,Gd})\text{BO}_3\text{:Eu}^{3+}$ or $\text{Y(V,P)O}_4\text{:Eu}^{3+}$, and $\text{BaMgAl}_{10}\text{O}_{17}\text{:Eu}^{2+}$ (barium magnesium aluminate (BAM [50,51]) to produce green, red, and blue colors, respectively [49]. These energy transfer mechanisms are under active investigation.

It is of utmost environmental interest to develop powerful mercury-free lighting systems that use the Xe_2^* excimer fluorescence followed by conversion to visible light applying selective phosphors. One of the first outcomes of intensive R&D in this field was the development of the flat panel lamp PLANON®† based on the DBD technology using xenon as excimer gas. This tile-like lamp has a maximum visual area of 320×320 mm and a thickness of only 10 mm. It exhibits a constant and bright and high luminance over the whole area, and a long lifetime. Therefore, it is unprecedentedly qualified for backlighting of LCD displays [19] that are used, for example, for GPS systems or for medical monitoring applications [52–54]. On the same basis, the development of the tubular lamp system Linex®‡ was described recently. This lamp generation represents an important milestone for the future application of mercury-free luminescent excilamp systems in general lighting [2]. Its fast response without any warm-up phase makes it ideally suitable for application in scanners, fax, and photocopy machines.

The main problems of the satisfactory development of luminescent excilamp systems for use as powerful lighting devices or as PDPs are directly related to the stability, absorption, and emission characteristics of the kind of luminescent material used. Up to date, most UV-emitting phosphors (e.g., BAM) have been optimized for excitation by the 254 nm line of low-pressure mercury fluorescence. However, recently Guivan et al. [55] reported on experimental results concerning the excitation of green, red, and blue phosphors by XeI^* excilamp radiation.

The Xe/Ne plasma discharge generates high-energy photons ($\lambda = 147$ and 172 nm) that cause degradation reactions and color shifts of BAM. Thus, main challenges of future research concentrate on the optimization of

the phosphors for use under VUV excitation. An intensive search for VUV-stable phosphors is still in progress. For example, a promising candidate as a blue-emitting phosphor is $\text{Ba}_5\text{SiO}_4\text{Cl}_6\text{:Eu}^{2+}$ [56], with its maximum of emission at 440 nm. A thulium cation-doped lanthanum phosphate phosphor (LPTM , $\text{LaPO}_4\text{:Tm}^{3+}$) exhibits a narrow band emission with its maximum at $\lambda = 452$ nm and several additional bands in the UV region of the electromagnetic spectrum [57]. The emission spectra of this material were studied by excitation with a Kr_2^* and a Xe_2^* excilamp, respectively. LPTM showed much higher stability against VUV-induced degradation compared to BAM . An europium cation-doped barium aluminate ($\text{BaAl}_2\text{O}_4\text{:Eu}^{2+}$) phosphor [58] exhibited a broad emission band between 425 and 650 nm, peaking at 500 nm under 172 nm excitation. Recently, Yuan et al. [59] investigated the VUV spectroscopic properties and the emission characteristics of a series of lanthanide cation-doped alkali rare earth diphosphates of the type $\text{AREP}_2\text{O}_7\text{:Ln}^{3+}$ (A: Na, K, Rb, Cs; RE: Y, Lu, La, Gd; Ln^{3+} : Ce, Pr, Tb, Eu, Tm). As a result of this study, they demonstrated that Tb^{3+} -doped NaREP_2O_7 , with RE being La or Gd, are potential candidates for green PDP phosphors under excitation by 172 nm. For 3D PDPs, short decay times of the phosphors and bright luminescence are essential. Thus, Zang et al. [49] presented a series of short-decaying phosphors of the types $\text{Y}_3\text{Al}_5\text{O}_{12}\text{:Ce}^{3+}$ (green), $(\text{Y,Gd})\text{Al}_3(\text{BO}_3)_4\text{:Tb}^{3+}$ (green), and $(\text{Y,Gd})_2\text{O}_3\text{:Eu}^{3+}$ (red), enabling for the first time switchable 3D/2D PDP television. The conversion of 172 nm radiation by UV-C emitting phosphors to germicidal radiation is also under active investigation [60]. Considerable research interests have focused on the so-called quantum cutting (QC) process (e.g., [61]). In this process, the absorption of a single VUV photon by the phosphor results in a cascade emission of two photons of lower energy (down conversion) [45]. Since the energy of a VUV photon is more than twice the energy of a visible photon, it should be possible to obtain two visible photons for each VUV photon absorbed. Special phosphors (two-photon phosphors) utilizing this effect are under development. Quantum efficiencies close to 200% have already been demonstrated with red ($\text{LiGdF}_4\text{:Eu}^{3+}$) and green ($\text{K}_2\text{GdF}_5\text{:Tb}^{3+}$) phosphors [62,63]. The combination of using efficient Xe_2^* excimer radiation with quantum cutting phosphors could further improve the efficiency of mercury-free fluorescent lamps and plasma displays.

2.2.2 Photomedicine

The mechanistic aspects, photochemical and photobiological effects of phototherapy and of photochemotherapy are areas of modern research in photoscience [64]. Sunlight therapy for skin diseases, for example, psoriasis, alopecia areata, vitiligo, atopic dermatitis, and eczema, has been applied empirically since antiquity [65]. Psoriasis is a skin condition that is characterized by red, scaly plaques covered with silvery scales. Alopecia areata is a disease that causes round patches of hair loss. Vitiligo describes a leucodermal condition, that is, white areas of skin from congenital or acquired absence or loss of melanin pigmentation. Phototherapy or photochemotherapy (i.e., psoralen + UVA, PUVA-therapy) for the treatment of such diseases use conventional medium-pressure mercury lamps with or without metal halide additives and/or optical filter systems, or mercury containing fluorescent tubes like the Philips TL01. The latter lamp emits a narrow band of UVB radiation around 311–312 nm [65]. In modern phototherapy, 308 nm xenon excimer lasers are successfully applied for the treatment of localized psoriasis [66]. However, recently a research group [67] of Osram Sylva Inc. described a novel Xe_2^* excilamp with a gadolinium cation-doped strontium magnesium aluminate phosphor ($\text{Sr}(\text{Al,Mg})_{12}\text{O}_{19}\text{:Gd}^{3+}$) that emits a narrow band of UVB radiation with its maximum at 310 nm. Thus, this fluorescent excilamp seems ideally suited for UVB phototherapy. In addition, since several years the XeCl^* excilamp with its emission maximum at 308 nm is extensively evaluated for these purposes [68,69]. It is applied in novel dermatological instruments called Excilite* (DEKA, Italy) [70] or VTRAC† (PhotoMedex, USA), which are under active investigation [71–77]. In fact, spectral measurements of the XeCl^* excilamp demonstrated that 50% of its radiant energy is located between 306 and 309.5 nm, whereas 90% is delivered by a narrow band between 298 and 312 nm [68]. An advantage of this XeCl^* excilamp apparatus over expensive laser systems is the possibility of treatment of large areas [78] of up to 504 cm² with a high irradiance of

50 mW cm⁻². This situation is accompanied by a significant shortening of the patient's sessions. Thus, perhaps the long-term risk of UV-induced carcinogenicity can be reduced significantly.

2.2.3 Surface Modification

VUV/UV irradiation of polymers is interesting for fundamental and applied sciences [79,80], materials processing [81], and nanofabrication technologies [82]. For example, polymeric materials are used as photoresists in semiconductor technology in combination with VUV radiation. Further, polymers are widely used in spacecraft technology. Thus, they are exposed to solar VUV/UV radiation in space and undergo specific photo-induced degradation reactions, for example, mass loss by ablation or etching. In addition, modern research concentrates on the VUV-induced modification of surface properties of polymers that are used extensively in medicine or biology to enhance their biocompatibility.

2.2.3.1 Biomaterials

Already in 1998, Cezeaux et al. [83] demonstrated that the VUV irradiation of expanded poly(tetrafluoro ethylene) (ePTFE Teflon) vascular grafts using an excilamp provides a better surface for endothelial cell proliferation. However, no effect of VUV treatment of the polymer on cell adhesion was observed. It is also possible to chemically modify polymer surfaces by the combined treatment with VUV photons and a reactive gas atmosphere [84]. Thus, the adhesion of smooth muscle cells from human aorta [85] and of human endothelial cells [86] on PTFE could be significantly enhanced by 172 nm irradiation with a Xe₂^{*} excilamp under an ammonia (NH₃)-containing atmosphere. This result is due to the creation of new polar functional groups (–C–NH₂, –C=O, –C–OH, –C–OOH) on the surface of the polymer by photochemically induced cleavage of C–F bonds followed by incorporation of N and O atoms. The changes of the surface structure of the PTFE sample were analytically established by x-ray photoelectron-, UV-Vis-, IR-spectroscopy, secondary ion mass spectrometry [86], and laser-induced fluorescence measurements [84,87]. It was also demonstrated that the VUV/NH₃ treatment of PTFE led to an enhanced surface polarity of the sample, which is correlated with its wettability by water. Contact angle measurements of water on the VUV/NH₃-treated PTFE surface verified this result. Additionally, grafting of the PTFE surface with amino acids directly after the VUV/NH₃ treatment supports the adhesion and proliferation of aortic smooth muscle cells and mouse 3T3 fibroblasts [87]. Thus, the VUV/NH₃-modified or amino acid-grafted PTFE was proposed as useful material for vascular prostheses [86] or for percutaneous implants or substrates for skin cultivation [88]. Similar techniques were used by Olbrich et al. [89] to improve the cytocompatibility of a novel nanocomposite polymer material that may have applications in tissue engineering. Interestingly, Mikulikova et al. [90] could produce cell microarrays on PTFE after VUV/NH₃ processing through thin nickel contact masks with holes of a diameter of only 100 μm and seeding of the cells on the surface. The cell adhesion and proliferation occurred only on the photochemically modified spots. This procedure may be useful for microarray techniques in advanced genomics and proteonomics [90].

Hozumi et al. [91] described a method for the spatially defined immobilization of bovine serum albumin (BSA) onto a microstructured surface of poly(methyl methacrylate) (PMMA). This was achieved after the VUV-initiated ablation of PMMA through a photomask using a Xe₂^{*} excilamp with generation of microwells of a depth of less than 400 nm and a diameter of less than 20 μm. The wells could be selectively filled with an aminosilane, which increases the bioaffinity to BSA. Catalase from bovine liver functionalized with an allyl group could be successfully immobilized on poly(ethylene terephthalate) after irradiation of the polymer with a KrCl^{*} excilamp [92].

2.2.3.2 Polymers

VUV photons are eligible for the treatment of polymer surfaces at low process temperatures [93]. The penetration depth of VUV photons into the polymer material is low due to the high absorbance of the latter. Thus, the bulk of the irradiated polymer is not affected by VUV radiation and morphological and chemical changes are limited to the surface of the material [30]. These changes are initiated by homolytic bond cleavages with formation of radicals or other transient species in the surface layers of the polymeric substrate. [Table 2.3](#)

summarizes significant contributions to this field of research. The extent of ablation (etching), for example, depends strongly on the absorbance characteristics of the polymer and the intensity and the wavelength of the impinging VUV radiation [94]. Of special interest in materials processing are methods of grafting a surface by photochemical generation of active sites on the polymer followed by exposure to gaseous reagents [95].

2.2.4 Surface Cleaning

VUV-induced cleaning of materials, for example, glasses for the manufacturing of liquid crystal displays (LCDs), mirrors for space applications, reticles used for photolithography, or silicon (Si) wafers used for semiconductor manufacturing can easily be performed by use of VUV excilamps, normally in Ar with traces of O₂ and H₂O. The mechanisms of this process for the removal of residual organic contaminants on the surface of a substrate include direct VUV photolysis of the organic matter, which is accompanied by formation of a highly oxidative atmosphere induced by photolysis of oxygen and water vapor, and further by photolysis of ozone. This atmosphere contains a series of reactive oxygen species (O(¹P), O(¹D), •OH, O₃). Thus, the chemical reaction scheme of advanced oxidation of hydrocarbons on surfaces was outlined by Falkenstein [117]. The complete oxidation of the organic matter results in the products H₂, H₂O, CO, and CO₂, which are removed by the carrier gas stream. Tode et al. [118] used

the direct irradiation of Si wafers with the VUV radiation of an Ar_2^* excilamp to remove surface-bound hydrocarbons in an argon atmosphere. Organic contamination on the surface of Si wafers could be eliminated by exposure to a Xe_2^* excilamp under ambient air conditions [119]. Alkyl monolayers on p-type Si wafers were decomposed by irradiation with a Xe_2^* excilamp [120]. Similarly, oxygen atoms could be removed from an oxidized silicon surface (SiO_2) on a Si wafer in a vacuum chamber using an Ar_2^* excilamp, thus enabling ultraprecise SiO_2 processing with formation of elemental Si [121]. On the other hand, silicon was oxidized with formation of SiO_2 dielectric films by Ar_2^* excilamp irradiation in the presence of O_2 [122].

2.3 Process Technologies

A large variety of modern technological applications use polymers or polymer-based materials covered by thin films of metals or dielectrics, for example, solar cell structures, printed circuit boards, silicon and semiconductor microelectronics, and optoelectronics. Thus, the demand for low-temperature processing of these polymers is evident. Consequently, excilamps are especially qualified for photo-CVD, UV curing, and photolithographic processes.

2.3.1 Photo-CVD

Metallic or nonmetallic thin films on various substrates may be produced by photo-induced chemical vapor deposition (photo-CVD) [123–125]. Already in 1989, Esrom et al. [126] demonstrated the deposition of palladium layers on Al_2O_3 or quartz by 172 nm irradiation of palladium acetate films using a Xe_2^* excilamp. Table 2.4 summarizes some recent developments in this area of research.

TABLE 2.4 Recent Examples of Photo-CVD Using Excilamp Radiation

2.3.2 UV Curing and Photolithography

UV curing of polymeric precursors is a typical part of “green” technology that uses photons of distinct energy for initiation of polymerization. A large variety of UV-curable materials, for example, inks, coatings, and adhesives, are available on the market. Research activities try to increase the curing efficacy, increase the speed of the process, and improve the physical-chemical properties of the curables. The use of excilamps in printing processes for UV curing was established by Mehnert [136]. A powerful XeCl^* excilamp with a maximum irradiance of 200 mW cm^{-2} was used in this study to cure offset inks with medium- to high-cure speed and without thermal stress for the material [32]. The lamp was developed by Heraeus Noblelight (Germany) [137]. Recent research focused on the radiation-induced polymerization of acrylates using a KrCl^* excilamp [138] without addition of any photoinitiator. Consequently, this process was scaled up by using a KrCl^* excilamp with an electrical input power of 10 kW and an irradiance of 175 mW cm^{-2} [139]. On the other hand, a new reaction concept was recently reported by Silveiras et al. [140]. This research group validated a photoreaction system that applies a pulsed XeCl^* excilamp for the production of prepolymer methyl metacrylate (MMA) of low polydispersity by photochemically initiated polymerization using benzoin as the photoinitiator. From a series of experiments, they concluded that the pulse frequency of the XeCl^* excilamp is an important factor for the polydispersity and the rate of production of the prepolymer MMA material. Photochemical matt finishing of acrylate coatings using a dual-lamp setup consisting of a Xe_2^* excilamp and a medium-pressure mercury lamp was described by Bauer et al. [141]. This technique produced a very natural optical appearance of the coating. Therefore, it seems to be predestinated for the finishing of durable parquet or PVC flooring.

Chip manufacturing relies on the development of photolithographic methods. The optical resolution (R) of these techniques is defined by the Rayleigh equation ($R = k_1 \times \lambda/\text{NA}$, NA: numerical aperture). Thus, as the wavelength of the radiation applied decreases, the optical resolution on a wafer decreases significantly. For example, Xe_2^* excilamps have been used for submicrometer patterning of photoresist films [142], monolayers of alkyl- and fluoroalkylsilanes on Si wafers [143,144], monolayers of chloromethylphenylsiloxane (CMPHS) [145], and polystyrene surfaces [110] and for the microfabrication of metal oxide films on polymer substrates [146,147].

2.4 Analytical Photochemistry

Trends of applications of excilamps as radiation sources in analytical instruments and of actinometric procedures for the measurement of their photon flux were summarized by Oppenländer [148]. Recent developments include the use of an Ar_2^* excilamp for the soft single photon ionization of organic molecules in an orthogonal acceleration time-of-flight mass spectrometer (oaToFMS) [149]. Batalova et al. [150,151] and Noskova et al. [152] reported on the use of XeBr^* and KrCl^* excilamps for the photochemical pretreatment of foodstuffs or urine to quantitatively determine the Hg^{2+} or the iodine content by polarographic analyses. Batalova et al. [153] also described an electrochemical version of the well known ferrioxalate actinometer [154] for the measurement of the photon fluxes of a KrCl^* and a XeBr^* excilamp. Sosnin et al. [155] presented an electrochemical version for the quantitative determination of the concentration of formaldehyde using the known methanol actinometer [156,157] in the photolysis of water with a Xe_2^* excilamp at 172 nm. Bark et al. [158] used the amount of H_2O_2 formed by irradiation of pure water for the calculation of the photon flux of their lamp system at wavelengths below 190 nm. Shen et al. [159] recently presented a model for the measurement of germicidal UV radiation of KrCl^* and XeBr^* excilamps in photoreactors by applying the photoconversion of (E)-5-[2-(methoxycarbonyl)ethenyl]cytidine to the violet fluorescent product 3- β -D-ribofuranosyl-2,7-dioxypyrido[2,3-*d*]pyrimidine. The concentration of the photoproduct was quantitatively monitored by fluorescence spectroscopy.

Actinometry with production of ozone by irradiation of oxygen with a Xe_2^* excilamp was applied by Laszlo et al. [160]. Recently, this method was optimized for the measurement of incident 172 nm

photons in an experimental setup used for aerosol functionalization [112]. In their experiments, Vicente et al. [112] reported that the generation of the photostationary O_3/O_2 composition was independent of the addition of H_2O using their Xe_2^* excilamp configuration. However, this result is in strict contrast to the work reported by Salvermoser et al. [161,162]. This group demonstrated a significant influence of trace amounts of water during 172 nm irradiation of oxygen in air on the stationary state concentration of ozone. Presumably, the formation of hydroxyl radicals ($HO\bullet$) and of hydroperoxyl radicals ($HO_2\bullet$) by 172 nm photolysis of water vapor initiates a catalytic cycle of O_3 destruction. These results were verified by a quantitative kinetic model that describes the influence of humidity on the photochemical production of O_3 [162]. The 172 nm photolysis of dry air yields very clean O_3 with high yield and without any NO_x impurities. Consequently, several sustainable applications of these novel Xe_2^* excilamp ozone generators for sterilization or odor control in food storage were proposed [162].

2.5 Synthetic Photochemistry

Unfortunately, the enormous potential of excilamps in synthetic photochemistry is still limited to some practical examples that were demonstrated by Griesbeck et al. [163,164] and Oelgemöller [165]. These authors concentrated on the use of a powerful $XeCl^*$ excilamp (electrical input power $P_{el}^{in} = 3\text{ kW}$) in a falling film photoreactor. They performed photodecarboxylations, $[2 + 2]$ -photocycloadditions, and Type III photooxygenations with high yields and isolation of gram quantities of photoproducts. On the other hand, industrial photochemical engineering successfully established the use of a $XeBr^*$ excilamp for the technical synthesis of Vitamin D3 by photolysis of 7-dehydrocholesterol [166] (see also [148]). An interesting paper from Terasaki et al. [167] deals with the photosynthesis of trace amounts of aspartic acid by 172 nm irradiation of an aqueous solution of urea and maleic acid. This is probably the first contribution of excilamp VUV photochemistry to studies elucidating the mechanisms of the formation of biomolecules on the primitive earth, that is, a contribution to prebiotic chemistry dealing with origin of life studies.

2.6 Destructive Photochemistry

In contrast to photochemically induced synthesis of complex structures, destructive photochemistry uses the energy of VUV or UV radiation to initiate the change or destruction of structural entities like organic molecules in water or air, or to inactivate microorganisms in these media. Several books describe the enormous efforts in advanced oxidation processes (AOPs) and advanced oxidation technologies (AOTs) [168–171], and in UV-disinfection technologies [172] to gain insight into the different aspects of the underlying complex mechanisms. Interestingly, excilamps are still not yet part of industrial applications in this area, with one exception: Triton Thalassic Technologies, Inc. (T^3I)* claims the development of an almost monochromatic light source for applications in the industrial UV disinfection of fluids [173]. This lamp possibly resembles a $XeBr^*$ [174,175] excilamp.

2.6.1 Surface Disinfection

Infection control by surface treatment is of utmost importance for public health in hospitals, vehicles, and public transportation including airplanes. Heise et al. [176] described a hybrid process by combination of flat $KrCl^*$ or $XeBr^*$ excilamps and a reactive DBD plasma to successfully inactivate spores of *Bacillus subtilis* and *Aspergillus niger* on PET foils. Similarly, Christofi et al. [177] reported the UV inactivation of *Staphylococcus aureus*, *Streptococcus pyogenes*, *Bacillus subtilis*, and *Aspergillus awamori*

* <http://t3i-uv.com/uv.html> (latest access: 12/06/2009).

spores, and clumps of *Mycobacterium phlei* deposited on membrane filters using a XeBr* excilamp. The energy needed to kill 99.9% (log 3 reduction) of film populations (3.4×10^5 to 9.5×10^5 colony forming units (CFU)/cm²) were 22, 18, 47, 387, and 27 mJ cm⁻², respectively.

2.6.2 UV Disinfection

UV-disinfection techniques rely on the damage of the DNA [178] of microorganisms by absorption of germicidal UV radiation ($200 \text{ nm} < \lambda < 300 \text{ nm}$) [172,179]. As a consequence, the microorganisms cannot replicate and thus cannot cause disease [180]. Recently, DNA damage was directly detected by an approach based on polymerase chain reaction (PCR) [181] during standardized UV disinfection with low-pressure mercury lamps. Several recent studies applied modern excilamps for UV-disinfection of aqueous media using various indicator microorganisms. One of the most widely studied candidates for this purpose is the XeBr* excilamp [175,182–187]. Its emission maximum is bathochromically shifted from the absorption maximum of DNA ($\lambda_{\text{max}} = 260\text{--}265 \text{ nm}$ [188]) by several nanometers. Fortunately, it also exhibits a hypsochromic tailing down to 260 nm [185]. The maximum germicidal effectiveness of UV-C radiation is located around 260 nm [172]. Thus, the efficiency of inactivation of microorganisms with a XeBr* excilamp compares to that of a low-pressure mercury lamp ($\lambda = 253.7 \text{ nm}$). Several recent studies deal with the effect of 222 nm radiation of KrCl* excilamps on microorganisms [189–192] or on enzyme systems [193]. Two separate studies demonstrated the effect of short wavelength UV-C radiation on microorganisms using a KrBr* excilamp [194] and the iodine atomic emission of an I₂* excilamp at 206 nm [195]. Wang et al. [196,197] compared the effectiveness of a Xe₂* and a KrCl* excilamp to that of a low-pressure mercury lamp on *Bacillus subtilis* spores. They found that the 222 nm radiation was more effective for the inactivation of *B. subtilis* spores than 254 and 172 nm. The two log reductions (i.e., by 99%) of *B. subtilis* required fluences of 21.6, 40.4, and 870 mJ cm⁻² at these individual wavelengths, respectively. The VUV exposure at 172 nm is much less efficient than at 222 and at 254 nm. This is due to a completely different mechanism that is active in 172 nm irradiation of water. Due to the high absorbance of water at this wavelength, only water absorbs the incident VUV radiation of the Xe₂* excilamp, which leads to homolytic cleavage of water molecules and subsequent formation of •OH radicals and hydrogen atoms (see Section 2.6.3). The latter are immediately scavenged by dissolved molecular oxygen with formation of hydroperoxyl radicals (HO₂•) that enter the oxidative radical cycle. Thus, in the case of the Xe₂* excilamp, the inactivation of *B. subtilis* spores seems to be due to the highly oxidative conditions of the radical species cocktail that is generated by water photolysis. However, this process of *B. subtilis* inactivation is inefficient in comparison to the photochemical reactions of DNA and of other cell components at 254 and 222 nm irradiation. Interestingly, *B. subtilis* spores did not show any inactivation under conditions of the H₂O₂-UV AOP [198]. Psychrophilic and mesophilic microorganisms of an opaque graywater were sensitive to VUV and UV radiation from Xe₂* and KrCl* excilamps [199].

2.6.3 Advanced Oxidation Processes

In 1987, Glaze et al. [200] introduced the term advanced oxidation processes (AOPs). It refers to the oxidation of contaminants in water or air that relies on the formation and reactivity of hydroxyl radicals (HO•). Several reviews describe the underlying hydroxyl radical-induced mechanisms of AOPs [201–207]. The understanding of the mechanisms of AOPs may be improved significantly by distinct modeling of the kinetic regimes that are involved [208,209]. In recent years, many experimental studies demonstrated the enormous potential of excilamps in AOPs. Especially, the complex reaction scheme that is initiated by water photolysis (H₂O-VUV, Reactions 1, 2; Table 2.5) at 172 nm with Xe₂* excilamps was investigated comprehensively during the past two decades. The results of these investigations were reviewed and critically judged by Gonzalez et al. [210]. Hydroxyl radicals are short-lived, highly reactive, and nonselective powerful oxidants. They exhibit electrophilic

character, are easy to produce, and are ubiquitous in nature. Most important, their reactivity is kinetically controlled (Table 2.5). Thus, as a rule of thumb, the overall rate of oxidation of a contaminant in water or air is approximately proportional to the second-order rate constant of the elementary reaction of hydroxyl radicals with this specific contaminant [204]. The second-order rate constants of hydroxyl radicals with many substrates are freely available on the Internet* or from Buxton et al. [211]. Some examples are summarized in Table 2.5. The reactivity of hydroxyl radicals toward organic substrates includes hydrogen abstraction (Reaction 3, Table 2.5) or electrophilic addition to double bonds (Reaction 4, Table 2.5) with the formation of carbon-centered radicals, and in some cases also electron transfer reactions [201]. Interactions of hydroxyl radicals with S-, N-, or P-atom containing functional groups in aqueous phase may lead to the formation of intermediary two center–three electron adducts [212]. These groups also affect the efficacy of hydrogen atom abstractions at adjacent carbon atoms [209]. Hydrogen atoms or solvated electrons formed by VUV photolysis of water are immediately scavenged by dissolved molecular oxygen (Reactions 5, 6; Table 2.5). A complex chain-like mechanism that involves the scavenging of carbon-centered radicals by dissolved molecular oxygen with formation of peroxy radicals [213,214] (Reactions 7, 8, Table 2.5) leads to the formation of oxidized intermediary products like aldehydes, carboxylic acids, and alcohols. This series of reactions occurs on the way to the complete mineralization of the organic substrates (Reactions 9–12; Table 2.5). Hydroxyl radicals also efficiently recombine with formation of hydrogen peroxide (Reaction 13, Table 2.5). The concentration of H₂O₂ formed during 172 nm irradiation of contaminated water depends strongly on the nature of the organic contaminant that is present in water [215]. However, the efficacy of the oxidation of organic substrates (i.e., diminution of substrate concentration) or their mineralization (i.e., diminution of the total organic

* The Radiation Chemistry Data Center of The Notre Dame Radiation Laboratory; <http://kinetics.nist.gov/solution/> (latest access: 08/22/2011).

carbon content, TOC) by VUV photolysis of aqueous reaction systems is extremely limited by the high absorbance A_λ of water below 190 nm. The linear absorption coefficient $\alpha_{172} = A_{172}/d$ of pure liquid water is 550 cm^{-1} [216] (d = optical pathlength or penetration depth). Due to the low penetration depth of 172 nm radiation into water, which is less than $100 \mu\text{m}$, the photoreaction takes place in a tiny photoreaction volume at the quartz–water interface. The production of a high local concentration of hydroxyl radicals subsequently leads to a high local concentration of carbon-centered radicals according to Reactions 3 and 4 (Table 2.5). The scavenging of these carbon-centered radicals by dissolved molecular oxygen generates an oxygen deficit within the irradiated volume. As a consequence, the efficacy of the TOC diminution according to Reactions 7–11 (Table 2.5) is inherently low. It is strongly dependent on the concentration of O_2 in the radical reaction zone. Two solutions for this problem have been proposed: a combination of a Xe_2^* photochemical irradiation unit with an electrochemical reactor to produce oxygen within the irradiation zone by water electrolysis was described by Braun et al. [210,217]. A much simpler technical concept was introduced by Oppenländer et al. [40]. This group used an axially mounted ceramic oxygenator for the injection of molecular oxygen or air directly into the irradiated volume of the Xe_2^* excilamp flow-through photoreactor (see Figure 2.5A and B). With this simple reactor concept, the efficacy of the TOC diminution by 172 nm irradiation of contaminated water samples could be increased drastically [40]. The use of a static mixer electrode (SME, Figure 2.5A), which was axially centered within the water flow of a Xe_2^* flow-through photoreactor, had almost no influence on the TOC diminution kinetics. But the SME enhanced the efficacy of the substrate oxidation by about 20%–30% compared to a spiral metal wire electrode. The substrate decrease (i.e., the oxidation) and the TOC diminution (i.e., the mineralization) during 172 nm irradiation of solutions of Rhodamine B and of methanol were independent of the temperature of the water in the range from 20°C to 60°C [218]. The present results of VUV photolysis of water with Xe_2^* excilamps open up a miniaturization strategy of photoreactor design similar to that described by Coyle and Oelgemöller [219].

The problems of VUV water photolysis are in contrast to VUV photolysis of gaseous media (Reactions 14–20, Table 2.6) where the absorbance is much lower and the diffusion coefficients are much higher than in aqueous media. Some of the relevant 172 nm initiated reactions of gaseous media are summarized in Table 2.6.

The enormous progress of research in AOPs of aqueous and gaseous systems using the excilamp technology is illustrated by various examples presented in Table 2.7.

2.7 Epilogue

The excilamp technology became mature during the past two decades. Although this modern lamp generation is still tested and improved, its potentials are obvious. In several cases, it moved out of researcher's laboratories to produce commercially useful applications. Unfortunately, everyday realities attest that the excilamps have not yet reached the standard photochemical laboratory. Up to date, the greatest hurdle of this development seems to be the fact that relatively cheap mercury containing low- or medium-pressure lamps are generally used in these laboratories (possibly with conventional filter systems). Therefore, a huge challenge of the future development of excilamps includes their cheap mass production. As with the development of other forms of lamps (e.g., LEDs), this way is influenced massively by economical aspects and by the environmental legislation related to the use or ban of mercury in lighting and UV-disinfection applications. Nevertheless, the author is confident that excilamps will play a significant role in several modern and sustainable photochemical and technological applications. Undoubtedly, excilamps are lamps of the future.

Acknowledgments

The author thanks Eszter Szakács (University of Szeged, Hungary) and Dr. Ulrich Kogelschatz for having read the chapter. The critical comments of Dr. Kogelschatz on the content and his stimulating suggestions are greatly acknowledged and appreciated. Further, he is grateful to Heraeus Noblelight GmbH (Hanau) for the emission spectra of the excilamps.

3.1 Introduction

Over the last decades, microtechnology has received a great deal of attention. Its application rapidly grows in many areas, as evident, for example, in electronics and engineering. The development of microstructured devices for chemical reactions was observed only within the last 10 years.^{1–12} Miniaturization of chemical reactors offers many practical advantages of relevance to the pharmaceutical and fine chemicals industry.^{13,14} Also, the possibility of preparing chemicals in the required volume at the point of use neglects the need to store and transport hazardous materials. The small scales of microreactions make them additionally advantageous for green chemistry.^{15–19} Since light is regarded as a “clean reagent,” organic photochemistry can likewise serve as a green synthetic method.^{20–23} The potential of organic photochemistry as a powerful synthesis method is furthermore well documented, and a number of elegant chemo- and enantioselective transformations with high chemical and quantum yields have been realized.^{24–26} The combination of microtechnology and photochemistry, that is, microphotochemistry, thus represents a promising and appealing new concept (Figure 3.1).^{27–29}

3.2 From Conventional (Batch) to Micro (Flow) Photoreactors

Immersion well reactors or chamber reactors (Figure 3.2) are most commonly used in conventional laboratory-scale photochemistry.³⁰ The total volume of such laboratory batch systems is typically limited to 1 L. As common light sources, single low-, medium-, or high-pressure mercury lamps are used in immersion well reactors, while an array of fluorescent lamps is used for chamber reactors.

The application of batch systems for photochemical reactions has a number of disadvantages. Depending on the spectroscopic properties of the chromophoric reagent, complete light absorption is

FIGURE 3.1 (See color insert.) The concept of microphotochemistry.

FIGURE 3.2 (See color insert.) Immersion well reactor (with courtesy of UV-consulting Peschl), chamber reactor (Rayonet) with Schlenk flask, and top-irradiation chamber reactor (Luzchem) with petri dishes.

typically observed within a narrow layer of the reaction solution (as expressed in the Beer–Lambert law). High dilutions are thus commonly applied to reduce this effect. In addition, photochemical processes occur most effectively closest to the light source, which limits the total irradiation volume of the reaction. Common lamps typically show emission of numerous wavelengths or of broad emission (± 50 nm) at the chosen wavelength. Therefore, optical filters must be frequently applied, which reduce the energy efficiency of the lamps. Electric losses due to the generation of heat further lower the energy efficiency and require the usage of intensive water or air cooling during operations. The limited lifetime of lamps (~ 2000 h) additionally causes significant installation, maintenance, and operation costs. Batch processes with fixed volumes cannot be easily automated and follow-up reactions or decompositions are frequently observed. The formation of polymeric films and iron deposits on immersion wells is also common. Some novel reactor types, for example, falling-film^{31,32} or spinning-disc reactors,^{33,34} can reduce these effects but have not been adopted widespread.

Many of these disadvantages can be overcome by carrying out photochemical transformations in microreactors or microchips (Figure 3.3), on demand equipped with miniaturized light sources. Many microreactor devices, including complete systems as the KeyChem-Lumino reactor, are now commercially available, although many researchers continue to custom build their own devices.

Microstructured reactors are (generally, but not absolutely) reactors with three-dimensional structures, the inner parameters of which are under 1 mm in size.¹ There are two main types of “closed” microreactors, namely serpentine reactors and falling-film reactors. These reactors consist of a solid support with one or more microchannels. “Open” reactors without solid base use flexible microcapillaries instead.

The main feature of “closed” serpentine reactors is the long channel length, which can range from several centimetres to over a meter. Longer channels can be used to increase residence times, thus

FIGURE 3.3 (See color insert.) Dwell device (Microglas), KeyChem-Lumino system (with courtesy of YMC), and falling-film reactor (IMM).

making them advantageous when prolonged irradiation is needed. On-chip mixing of reagents can be achieved using separate inlets. Multilane microreactors have also been developed and can be used for scale-up.

Falling-film reactors were specifically designed for gas–liquid reactions.³⁵ The central element of its design is the reaction plate on which parallel microchannels are arranged. In these channels, the liquid phase generates thin falling films that move by gravity force. The large interfacial area of up to $20,000\text{ m}^2/\text{m}^3$ guarantees efficient saturation of the film with reactant gas that is flowing over the liquid phase. In contrast, closed channel devices require presaturation of the reaction mixture with reagent gas. Scale-up can be realized using cylindrical falling-film reactor models or larger channel plates.

The advantages of photochemical synthesis in microdimensioned reaction vessels were first discussed by Porter and Volman, although for batch systems.³⁶ Microstructured flow systems have additional characteristics, which make them beneficial for photochemical processes. The thin layers of the microchannels ($100\text{--}1000\text{ }\mu\text{m}$) ensure extensive penetration of light throughout the reaction mixture, even for relatively concentrated solutions. Microstructured devices also have a large surface-area-to-volume ratio that provides fast heat and mass transfer. The typically continuous flow mode circumvents undesired side reactions or decompositions caused by follow-up reactions. The starting reagents may be mixed directly online in a mixing channel preceding the actual reaction channel. The reagents can also be introduced to the reaction region in a specific sequence, thus removing the necessity for premixing. The irradiation time in a microreactor is easily changed, as it is directly proportional to the flow rate of the system. By changing the flow rate, product formation can be precisely controlled. The small experimental scale of microreactions reduces the total amount of waste and only requires small amounts of solvents and chemicals. The microreactor design also allows online UV³⁷ or IR monitoring³⁸ of the reaction. The small reactor size enables employing miniaturized or compact energy-saving light sources such as light-emitting diodes (LEDs).^{39,40} The processes in microreactors and the microreactor itself are safer in operation and can be automated. Likewise, the reactions proceeding in a small volume can be controlled much more easily with respect to pressure, temperature, and residence time.⁴¹ Thus, the risk of highly exothermic or explosive reactions can be reduced drastically. Microreactors can be operated in series or in parallel clusters for scale-up or optimization studies. Parallel networks of microreactors offer an efficient route to generate product volume on demand at the point of use.

3.3 Photochemical Reactions in Microreactors

A number of examples concerning photochemical performances in microreactors already exist in the literature.^{27,28} Based on the conditions required, these reactions can be divided into three basic categories: homogeneous reactions (the reagents are all in the same phase, i.e., in solution), heterogeneous reactions (reactions between liquid and gaseous reagents), and catalytic reactions (reactions that involve heterogenic catalysis).

SCHEME 3.1 Photopinacolization of benzophenone.

3.3.1 Homogeneous Reactions

3.3.1.1 Photopinacolization

The photopinacolization is one of the earliest photochemical reactions that was investigated in microstructured reactors with online UV detection. Jensen and coworkers studied the transformation of benzophenone **1** using isopropanol as solvent in two house-made microreactors (Scheme 3.1).³⁷ One reactor was fabricated by bonding a patterned silicon wafer to a Pyrex plate. The second reactor had a sandwich structure of a silicon wafer between two quartz wafers and allowed irradiation with lower wavelengths. In this investigation, a miniaturized fluorescent UV lamp was used as a light source.

For greater conversions to benzopinacol **2**, longer residence times or lower flow rates were required. No detectable product formation was obtained for flow rates greater than $10\ \mu\text{L min}^{-1}$. With reduced flow rates, the conversion improved. An adequate flow rate was established to be $4\ \mu\text{L min}^{-1}$ and showed conversions of up to 60%. At flow rates lower than $3\ \mu\text{L min}^{-1}$ product **2** tended to crystallize in the microchannel, thus clogging the device. The progress of the reaction was monitored off-chip using HPLC analysis and online using UV spectroscopy. The concentration of benzophenone was 0.5 M, which is relatively high for photochemical reactions. The use of these concentrated solutions effectively demonstrated the general advantage of microstructured reactors, as the shallow channel depth of $500\ \mu\text{m}$ enabled complete irradiation of the reaction mixture.

3.3.1.2 Barton Reaction

The preparation of the steroidal product **4** from substrate **3** via the Barton reaction (Scheme 3.2) was selected as a model reaction for microreactor testing.^{42,43} This reaction is of importance because product **4** is a key intermediate for the synthesis of myriceric acid A (an endothelin receptor antagonist). The experiments were carried out in a glass-covered stainless steel microreactor Type A or Type B (manufactured by Dainippon Screen Mfg). Microreactor Type A had a one-lane channel of $1000\ \mu\text{m}$ width, $107\ \mu\text{m}$ depth, 2.2 m length, and a hold-up volume of 0.2 mL. It was used for the initial process optimization. Microreactor Type B had 16 lanes with a channel $1000\ \mu\text{m}$ wide, $500\ \mu\text{m}$ deep, 0.5 m long, and a hold-up volume of 4 mL. This reactor type was used for multigram-scale production.

The initial work was concentrated on increasing reaction output through an optimized and energy-saving experimental setup. Therefore, the application of three different types of transparent glass covers (quartz, soda lime glass, and Pyrex) and two light sources (300 W high-pressure Hg lamp and 15 W

SCHEME 3.2 Barton reaction.

black light) were investigated. It was determined that Pyrex was most suited to the desired 15 W black light source. Due to the thermal instability of product **4** at temperatures greater than 50°C, the authors also examined the temperature dependence and the distance between the microreactor and the light source. Under optimized conditions, a residence time of 12 min furnished the desired product **4** in a yield of 71%. In an extension of this study, the same authors examined a UV-LED panel (48 pieces \times 35 mW) as a light source suitable in combination with microreactor Type A. After a residence time of 12 min, the desired product **4** was isolated in a yield of 70%. This result clearly demonstrated that UV-LEDs, despite their low intensity (compared to high-pressure mercury lamp), have sufficient strength to initiate photochemical processes. The authors also reported a gram-scale synthesis of the target compound using two microstructured reactors Type B connected in series and coupled with 8×20 W black lights. After constant operation for 20 h, the amount of product **4** isolated was 3.1 g (60% yield). Encouraged by the successful gram-scale synthesis, Sugimoto and coworkers focused their forthcoming work on the development of practical and automated multigram-scale synthesis.⁴³ For this research, they used an automated photomicroreactor system, DS-AMS-1 (manufactured by Dainippon Screen Mfg). This system provided operation monitoring via PC software and moreover had important safety functions. It employed one set of a Type B microreactor and six small (15 W) black light lamps. After continuous operation for 40 h, product **4** was obtained in an amount of 5.3 g (61% isolated yield). This clearly demonstrated the potential for numbering up of microstructured reactors and process optimization for the larger scale production of chemicals.

3.3.1.3 Photocycloaddition Reactions

3.3.1.3.1 Photochemical [2 + 2] Cycloaddition of Cyclohex-2-Enone with Vinyl Acetate

The photochemical [2 + 2] cycloaddition reaction is one of the most powerful and versatile methods for the formation of four-membered rings and has been extensively applied in organic synthesis.^{24–26} Fukuyama and coworkers selected the photochemical [2 + 2] cycloaddition of cyclohex-2-enone **5a** with vinyl acetate **6a** as a model reaction (Scheme 3.3) for testing in a commercially available microreactor dwell device (FOTURAN® glass, manufactured by mikrogilas).⁴⁴ This reactor has a channel of 500 μ m depth, 1000 μ m width, and 1.4 m length.

A regular 300 W high-pressure mercury lamp was used as a light source in this study. After 2 h of irradiation (flow rate of 0.5 mL h⁻¹) a GC yield of 88% for the desired product **7a** was obtained. Under the same conditions, the batch reactor (10 mL Pyrex flask) furnished only 8% of **7a**. The same reaction was repeated with two microreactors in series at a flow rate of 1 mL h⁻¹, which resulted in a similar isolated yield of 85%. Thus, microstructured reactors can shorten irradiation times and increase yield at the same time.

In an extension of the work, the suitability of the photochemical [2 + 2] cycloaddition for micro-flow conditions was further verified and two additional cyclohexenones, **5b** and **5c**, and two additional alkenes, **6b** and **6c**, were examined (Scheme 3.4).

In all cases examined, the corresponding cycloaddition products **7b–e** were obtained in yields of 47%–70% as regioisomeric mixtures.

88% GC yield in μ -reactor
8% GC yield in batch

SCHEME 3.3 Photochemical [2 + 2] cycloaddition of cyclohex-2-enone with vinyl acetate.

SCHEME 3.4 Photochemical [2 + 2] cycloaddition of cyclohexenones with alkenes.

3.3.1.3.2 Diastereoselective [2 + 2] Photocycloaddition of a Chiral Cyclic Enone with Cyclopentene

Asymmetric photoreactions are of special importance due to the formation of potentially biologically active natural products and unique structural compounds.^{45,46} Hence Ryu and colleagues explored the utility of a microflow system in photoinduced asymmetric reactions and compared the results with those obtained using a larger volume batch reactor.⁴⁷ The model reaction examined was the reaction of the cyclohexenonecarboxylate derivative **8**, which incorporated a (–)-8-(phenyl)menthyl group as a chiral auxiliary, with cyclopentene **9** (Scheme 3.5).

A microreactor with a single channel of 1000 μm \times 100 μm \times 2.2 m (width \times depth \times length) and a hold-up volume of 0.2 mL (Dainippon Screen Mfg) was employed. A simple Pyrex test tube with an inner diameter (ID) of 13 mm was used for the batch comparison test. Both systems were irradiated simultaneously by a common high-pressure Hg lamp. The photoreaction in the microflow system reached completion in 0.5 h, which was two times faster than in the batch system (1 h). However, the ratios of stereoisomers **10** and **11** were almost identical in both systems. Additionally, the authors investigated the

SCHEME 3.5 Diastereoselective [2 + 2] cycloaddition of a chiral cyclic enone and cyclopentene.

effect of temperature on the diastereoselectivity. The highest diastereoisomeric excess values of **10** (82%) and **11** (54%) were observed in the microflow reaction at -40°C . This was explained by a more accurate temperature control in the microflow system associated with a very large surface-area-to-volume ratio of the reaction chamber. In summary, this study has shown that a flow microreactor can be used for asymmetric photoreactions.

3.3.1.3.3 Intramolecular [2 + 2] Photocycloaddition of a 1-Cyanonaphthalene Derivative

Continuous flow microreactors have also been used in regioselectivity studies. The intramolecular $[2\pi + 2\pi]$ photocycloaddition of 1-cyano-2-((3-methyl-2-butenyloxy) methyl) naphthalene **12** in acetonitrile has been reported by Maeda et al. (Scheme 3.6).⁴⁸ The authors in particular compared the regioselectivity and efficiency for batch and microstructured reactor conditions.

The transformation was performed in custom-built reactors made from poly(dimethylsiloxane) with channels 300 μm wide, 50 μm deep, and 45 or 202 mm long. The reaction mixture was pumped through the microchannel at two flow rates of 0.03 and 0.05 mL h^{-1} and was irradiated by a xenon lamp coupled with a UV-29 filter. The channel pathlength of 202 mm afforded prolonged reaction time and was found as optimal. After an irradiation time of 3.4 min, the intramolecular photocycloadduct at the 1,2-position of the naphthalene ring **13** and the photocycloadduct at the 3,4-position **14** were detected in a ratio of 55:7 in the microreactor, respectively. In contrast, only 5% of photocycloadduct **13** and traces of photocycloadduct **14** were noticed under batch conditions after the same reaction time. This reaction was also investigated in the batch system with a longer residence time of 180 min and photocycloadducts **13** and **14** were detected in a ratio of 56:17, respectively, but the regioselectivity was still not as good as in the microreactor. The improved regioselectivity in the microreactor was explained by the flow mode. The initially formed cycloadduct **13** is continuously removed from the system, therefore reducing photocycloreversion to **12**. Extended irradiation times gave higher yields of **14** since reversion to the starting material does not take place for this compound. The enantioselectivity was also investigated using $\text{Eu}(\text{hfc})_3$ and a small but significant enantiomeric excess of 2% (e.e.) was determined.

3.3.1.3.4 Intramolecular [2 + 2] and [2 + 3] Photocycloadditions of 2-(2-Alkenyloxymethyl)-Naphthalene-1-Carbonitriles

Mizuno and coworkers examined other intramolecular photocycloadditions of 2-(2-alkenyloxymethyl)-naphthalene-1-carbonitriles **15a–c** (Scheme 3.7).⁴⁹ This investigation included a comparison to a batch reaction (Pyrex tube with a diameter of 8 mm) and a study on the effects of substituents, solvent, residence time, flow rate, and the microchannel dimensions.

Two microreactor types were utilized. The first (Type A) microreactor was commercially available (ICCDI05, Institute of Microchemical Technology), and was made from Pyrex glass with a channel of 100 μm width, 40 μm depth, and 120 mm length. A second (Type B) microreactor was made in-house from Pyrex plates and had a channel width of 2.5 mm, a depth of 50 μm , and a length of 60 mm. A 500 W xenon lamp was used as a light source.

SCHEME 3.6 Intramolecular $[2\pi + 2\pi]$ photocycloaddition of 1-cyano-2-((3-methyl-2-butenyloxy)methyl) naphthalene.

SCHEME 3.7 Intramolecular photocycloaddition of 2-(2-alkenyloxymethyl)-naphthalene-1-carbonitriles.

The irradiations performed in the microreactors allowed for increased regioselectivity and the initial photoproducts **16a-c** were selectively formed, while undesirable photocycloreversions yielding **17a-c** were suppressed. Additionally, higher conversions of 69%–75% were achieved in the microreactors after just 1 min, while the batch reactor showed a lower conversion of 74% after 3 h of irradiation. The increase in efficiency was explained by the better light penetration through the reaction medium in the microreactors compared to the batch system. It was also demonstrated that wider channels can significantly increase output while maintaining a shallow channel depth.

3.3.1.3.5 Intramolecular [2 + 2] Photocycloaddition of a Coumarin Derivative

Abbott Laboratories have recently designed a convenient flow-based photochemical microreactor named LOPHTOR.⁵⁰ The unique aspect of this new tool was its integration with an autosampler that enabled a set of conditions to be programmed and executed without human intervention. The reaction microchannels of 1000 μm width, 250 μm depth, and 3.93 m length were fabricated from stainless steel that contained integrated cooling channels on the back side. The total volume of the serpentine flow cell channels was 0.98 mL and it was sealed during operation by a fluorinated ethylene propylene (FEP) membrane using nitrogen. This membrane also created a transparent cover of the channel. A medium pressure mercury arc lamp (450 W) with concentrator and cold integral mirror was used for irradiation. On demand, selective wavelength filtering could be provided by a set of uranium-doped quartz plates.

The utility of LOPHTOR for photochemical synthesis was evaluated by the authors using the known intramolecular [2 + 2] cycloaddition of coumarin derivative **18** (Scheme 3.8) as model reaction. For comparison purposes, the same transformation was attempted in a batch mode, that is, in the roundbottom flask fitted with a magnetic stirring bar and condenser.

Initially, Vasudevan and coworkers investigated the dependency between product yields and residence time. Complete conversion of starting material **18** was achieved after 2 h in the microreactor and product **19** was isolated in a yield of 98%. In contrast, a much lower product yield of 30% was obtained

SCHEME 3.8 Intramolecular enone photocycloaddition.

in the batch system even after prolonged irradiation for 24 h. The substrate portfolio was subsequently expanded and the reaction procedure was applied to other coumarin derivatives. In all cases examined, a similar tendency was established. The product yields were significantly lower using the conventional batch photochemical setup, despite longer reaction times, and were characterized by extensive formation of side products.

The effect of the reactant concentration on the conversion of **18** to **19** was also evaluated. Five different concentrations of **18** in the range from 0.085 to 0.425 M were tested and no decrease in conversion rate was observed. This provides a convenient manner for scale-up of this process to generate hundreds of milligrams of material that will ideally suit early drug discovery applications.

3.3.1.3.6 Photochemical [2 + 2] Cycloaddition of Maleimide with 1-Hexyne and Intramolecular [5 + 2] Photocycloaddition of 3,4-Dimethyl-1-Pent-4-Enylpyrrole-2,5-Dione

The application of continuous flow technology to perform organic photochemistry on large scale was investigated by Booker-Milburn et al.⁵¹ The main focus of this research was to show the superiority of a continuous flow system over a batch reactor with respect to the product quality, 24 h isolated yield, and nonstop functionality. This is one of the first research studies on photochemistry where simple UV-transparent FEP tubing was used as the reaction vessel. The authors described this system as a flow reactor rather than a microreactor. However, during the reactor design optimization FEP tubing with an inner diameter of 700 μm and an outer diameter (OD) of 1100 μm was used, which defines the reactor as a microchannel. Four different flow reactors were constructed with hold-up volumes from 60 up to 280 mL, which were entirely determined by the tubing length and dimensions. In two of these designs, FEP tubing with the aforementioned diameter was employed. Being interested in multigram output, Booker-Milburn and coworkers considered wider tubing with the dimensions 2700 μm ID \times 3100 μm OD as optimal. One to five layers of this tubing were wrapped around a standard Pyrex or Vycor filter. An immersion well equipped with a 400 or a 600 W medium pressure Hg lamp as light sources was used as a base for this construction.

These reactors were assessed using the [2 + 2] photocycloaddition of maleimide **20** with 1-hexyne **21** to the cyclobutene product **22** and the intramolecular [5 + 2] photocycloaddition of 3,4-dimethyl-1-pent-4-enylpyrrole-2,5-dione **23a** to the bicyclic azepine **24a** as model systems (Scheme 3.9). Using an

SCHEME 3.9 [2 + 2] and [5 + 2] cycloaddition reactions of maleimide and its derivatives.

optimized system with three layers of FEP tubing and a Vycor filter, these reactions were performed with outstanding results compared to common batch reactors. A 0.4 M solution of the maleimide **20** underwent 83% conversion at 0.8 mL min⁻¹ flow rate representing a projected yield of the desired cyclobutene **22** of over 685 g/day. At the same flow rate a 0.1 M solution of compound **23a** was irradiated and the bicyclic azepine **24a** was isolated in a yield of 80%. This remarkable result represents a 24 h yield of 178 g of **24a**.

Using flow reactors, the residence time could be tuned by adjusting the volume of the reactor and the flow rate. Following this strategy, problematic photochemical reactions could be performed continuously, achieving the highest possible yield of product and limiting by-product formation. To demonstrate this principle, the authors selected the intramolecular [5 + 2] photocycloaddition reaction of 3,4-dichloro-1-pent-4-enyl-pyrrole-2,5-dione **23b** to the bicyclic azepine **24b** and tested it in flow and batch setups. As expected, the desired azepine **24b** was obtained in significantly higher yield in the flow reactor (45 g) compared to the batch system (0.5–1 g). The reactor was also applied to the protecting-group-free synthesis of (±)-neostenine using the [5 + 2] photocycloadditions as a key step.⁵²

3.3.1.4 Photodimerization of Maleic Anhydride

An important example of a problematic photochemical reaction is the photodimerization of maleic anhydride **25** (Scheme 3.10). It is known that this reaction yields the insoluble cyclobutane tetracarboxylic dianhydride (CBTA) **26**, which is used as raw material for polyimide and for alignment films for liquid crystal displays. This reaction was selected by Yoshida and coworkers as a model reaction for a novel liquid/gas slug flow microreactor.⁵³

The microreactor approach demonstrated that the clogging problem within the reactor can be overcome by a combination of slug flow and ultrasonication. Inert N₂ gas introduced into the solution flow as a spacer swept through the reactor tube and transported precipitated products in the liquid segments. At the same time, ultrasound vibrations inhibited the adhesion and sedimentation of precipitate within the reactor tube. FEP tubes of various sizes were used as the reaction vessel and the impact of the tube dimensions on product conversion was examined. Additionally, the effects of maleic anhydride concentration and residence time were also investigated. A standard 400 W high-pressure Hg lamp was employed as a light source. The experimental results showed that a 10% solution of maleic anhydride **25** underwent a satisfactory conversion of 70% after a residence time of 22 min in a FEP tube of 1.4 mm OD and 0.8 mm ID, respectively. The quality of the desired product **26** in the microreactor was of higher purity when compared to that from the batch system (cylindrical glass vessel with an ID of 75 mm and a height of 300 mm). Moreover, the unique design of the slug flow microreactor made it adaptable for continuous circulation and recycle operation. This allowed for an improvement of conversions and reduction in maleic anhydride waste. The slug flow microreactor was operated continuously for over 16 h without clogging.

3.3.1.5 Diastereodifferentiating Addition of Methanol to (R)-(+)-(Z)-Limonene

Another example of asymmetric synthesis performed in microreactors was the toluene-sensitized photoaddition of methanol to (R)-(+)-(Z)-limonene **27** (Scheme 3.11) as reported by Sakeda et al.⁵⁴ This transformation occurs with the formation of three addition products: *cis*- and *trans*-4-isopropenyl-1-methoxy-1-methylcyclohexane (*cis* **28** and *trans* **29** isomers) and exocyclic isomer **30**. Compared to

SCHEME 3.10 Photodimerization of maleic anhydride.

SCHEME 3.11 Diastereodifferentiating photosensitized addition of methanol to (*R*)-(+)-(*Z*)-limonene.

a microbatch cell, the authors found faster reactions and higher diastereomeric excess (d.e.) values in microchanneled reactors.

Three kinds of quartz microreactors (Shimadzu Co.) with channel sizes of $500\ \mu\text{m} \times 300\ \mu\text{m} \times 60\ \text{mm}$, $400\ \mu\text{m} \times 40\ \mu\text{m} \times 100\ \text{mm}$, and $200\ \mu\text{m} \times 20\ \mu\text{m} \times 100\ \text{mm}$ (width \times depth \times length) and a quartz batch cell with a total volume of 1 mL (light passlength of 3 mm) were utilized for this study. Irradiations were conducted using a low-pressure mercury lamp (40 W, 254 nm). The irradiation time within the microchannels was controlled by the injection rate of the syringe pump. The yield of *cis* and *trans* isomers increased linearly during the examined irradiation period of 135 s within the microreactors. In contrast, the yield in the batch cell increased linearly only up to 20 min and reached a plateau. Furthermore, the diastereomeric excess value was 30.6% (36 s of irradiation) in the microreactor while it was 28.7% (15 min of irradiation) in the batch cell. The origin of the difference observed for the d.e. value in the MR versus the batch cell was clarified by the estimated reaction constants for *cis* and *trans* isomer formation. These constants were significantly higher for the microchannels than for the batch chamber. In addition, a comparison study on the effect of the channel size on the photon efficiency was performed. Photon efficiency increased with decreasing channel size and was greater for the microreactors (0.11–0.29) than the batch system (0.06). The superior performance of the microreactor was explained by a better light penetration, the higher spatial illumination homogeneity, short exposure times, and a fast and continuous product removal from the irradiated area, which suppressed side reactions.

3.3.1.6 Continuous-Flow Synthesis of Vitamin D₃

The first example of a combined photochemical and thermal reaction in a microreactor was described recently by Takahashi et al.⁵⁵ The two-step conversion of provitamin D₃ **31** to vitamin D₃ **33** via previtamin D₃ **32** was selected as a model transformation in this study (Scheme 3.12).

The first step of this transformation is a photochemical one and was carried out in a custom-made quartz microreactor with a channel 200 μm deep, 1 mm wide, 250 mm long, and with a volume of 50 μL . For the second step, a microreactor that enabled simultaneous photo- and thermal reactions was utilized. Its microchannel was 200 μm deep, 1 mm wide, and 500 mm long and had an internal volume of 100 μL .

SCHEME 3.12 Two-step conversion of provitamin D₃ to vitamin D₃.

Those two microreactors were connected via polyetheretherketone (PEEK) tubing and employed a single 400 W high-pressure mercury lamp. The first reactor was irradiated through a Vycor filter (313–578 nm). The second reactor was irradiated through a combination of a Vicor and glass UV filters (360 nm) and was placed in a hot oil bath (100°C). Using this setup, an optimization study on the reaction conditions, in particular the solvent, concentration, and flow rate, was carried out. A fairly concentrated 30 mM solution of provitamin D₃ in 1,4-dioxane was introduced at a flow rate of 5 $\mu\text{L min}^{-1}$ with a syringe pump. After chromatographic purification, the desired vitamin D₃ **33** was obtained in a yield of 32% (HPLC-UV yield: 60%), which was significantly higher compared to the existing industrial process, where the yield of vitamin D₃ is below 20%.³⁰ The parallel application of photo- and thermal conditions within the second step of the vitamin D₃ synthesis shifted the equilibrium of the competing photoisomerization of the side product tachysterol (not shown) toward previtamin D₃ **32**. Moreover the generation of second undesired product lumisterol (not shown) was suppressed to less than 10%. Consequently, the microflow synthesis of vitamin D₃ did not require any purification of intermediates or high-dilution conditions, thereby reducing the amounts of waste.

3.3.1.7 Photodecarboxylative Benzylations of Phthalimide

Recently, Oelgemöller et al. have studied photodecarboxylative benzylations of phthalimide under batch and microflow conditions.⁵⁶ The benzylated hydroxyphthalimidines **36a** and **36b** were synthesized from the corresponding phenylacetates **35a** or **35b** and phthalimide **34** (Scheme 3.13), respectively.

Conventional batch transformations were performed in a Pyrex Schlenk tube (volume 100 mL) that was irradiated in a Rayonet chamber reactor equipped with 16 UVB fluorescent lamps (8 W each, $\lambda = 300 \pm 25$ nm). The dwell reactor (mikroglas) was made from FoturanTM glass and consisted of a (bottom) serpentine reaction channel (0.5 mm depth, 2 mm width, and 1.15 m length) and a top heat-exchanging channel. The microreactor was placed under a UV panel (Luzchem) fitted with five UVB lamps. Only two reactions were tested under micro conditions and improved yields of 97% (**36a**) and 98% (**36b**) were achieved after 2 h. Despite its larger lamp power, the batch reactor gave somewhat lower yields of 92% (**36a**) and 80% (**36b**) after an extended irradiation period of 3 h. The cosolvent acetone (50 Vol-%) functioned as a sensitizer and the improved performance in the microreactor was thus explained by a better light penetration through the solution. The same authors extended their study to other intra- and intermolecular photodecarboxylation reactions involving phthalimides and alkyl phenylglyoxalates.^{57,58}

3.3.1.8 Photoaddition of Isopropanol to Furanones

Oelgemöller and coworkers have also investigated the 4,4'-dimethoxybenzophenone (DMBP)-sensitized addition of isopropanol **38** to furanones **37a–c** (Scheme 3.14).^{59–61} The reaction was chosen as a model for a microreactor comparison study. Three types of microstructured reactor setups were examined; the dwell device (described in Section 3.3.1.7) under a UVA-panel (5 \times 8 W), a microchip (Micronit

SCHEME 3.13 Photodecarboxylative addition of phenylacetates to phthalimide.

SCHEME 3.14 Sensitized isopropanol addition to furanones.

Microfluidics) incorporating a panel of 365 nm high-power UV-LEDs (6×75 mW), and an in-house microreactor that consisted of two parallel PTFE capillaries wrapped around a Pyrex tube containing a single UVA-lamp (1×8 W) in its center. Conversion rates of **37a–c** were determined by NMR spectroscopy. The results from the microflow systems were compared to those in a conventional test tube irradiated in a batch chamber reactor (Rayonet, 16×8 W).

The batch system, the dwell device, and the microcapillary reactor gave high to almost complete conversions to **39a–c** after just 5 min of irradiation. Despite its weaker light sources, the microchip reached high conversions already after 2.5 min. Based on the conversion rates, reactor geometries and energy efficiency calculations the microreactor systems gave superior results compared to the batch process. Of the three microreactor designs examined, the LED-driven microchip gave the best overall results. This was explained by the highest light transmission through the very shallow reaction channel of the microchip ($150 \mu\text{m}$ depth), compared with the wider channel of the dwell device ($500 \mu\text{m}$ depth) and the inner diameters of the microcapillary ($558 \mu\text{m}$) and the test tube (9 mm), respectively. However, the capillary reactor was seen as the best setup in terms of handling and improvement potential.

3.3.1.9 Photocyanation of Pyrene

The photocyanation of pyrene **40** (Scheme 3.15) across an oil/water interface has been described by Ueno and coworkers.⁶² This transformation was performed in microchips made in-house from polystyrol substrate, with channel width of $100 \mu\text{m}$, depth of $20 \mu\text{m}$, and length of 350 mm . The reactors had either two or three inlets to the serpentine reaction channels. This allowed for a separate introduction of the oil and water phases, with equal flow rates, thus ensuring formation of stable water/oil or water/oil/water interfaces, respectively. The microchips were irradiated with light from a high-pressure mercury lamp (300 W) through a copper sulfate solution filter ($>330 \text{ nm}$).

An aqueous solution of sodium cyanide (1 M) and a solution of pyrene **40** (20 mM) and 1,4-dicyanobenzene (DCB, 40 mM) in propylene carbonate were pumped through the reactors. The product, 1-cyanopyrene **41**, remained in the oil layer. After a residence time of 210 s , the photoproduct **41** was obtained in yields of 28% for the oil/water system and 73% for the water/oil/water system, respectively. Below a flow rate of $0.2 \mu\text{L min}^{-1}$ no stable oil/water interface could be obtained, which prevented further improvement of conversion rates and consequently yields.

SCHEME 3.15 Photocyanation of pyrene.

3.3.2 Heterogeneous Reactions

The heterogeneous reactions are characterized by interactions between liquid and gaseous reagents. It is thus necessary to continuously provide a supply of reagent gas to the reaction media. The falling-film-type reactor was especially designed for the purpose, but other reactor systems have been utilized as well.

3.3.2.1 Photooxygenation Reactions

3.3.2.1.1 Photochemical Generation and Addition of Singlet Oxygen to α -Terpinene

The first study concerning the safe synthesis of the potentially explosive endoperoxide in a microreactor was reported by Wootton et al.⁶³ The photochemical synthesis of ascaridole **43** proceeds via addition of singlet oxygen to α -terpinene **42** in the presence of an organic dye as sensitizer (Scheme 3.16). This reaction requires sufficient oxygen saturation and therefore large quantities of oxygenated organic liquids with explosive nature are often formed in conventional conditions.

The reactor was built in-house from a glass substrate and consisted of two inlets at the start of the serpentine irradiation area (total length 50 mm, average depth of 50 μm , and average width of 150 μm) and an outlet channel. A methanol solution of α -terpinene and Rose Bengal was introduced via a divergent inlet channel with a flow rate of 1 $\mu\text{L min}^{-1}$ and mixed with oxygen on-chip (flow rate of oxygen of 15 $\mu\text{L min}^{-1}$). This design made presaturation of the α -terpinene solution with oxygen unnecessary. Irradiation was performed using an unfiltered tungsten lamp (20 W, 6 V). The small volume of aerated solvent in the system together with nitrogen degassing of the product mixture at the outlet avoided accumulation of oxygenated solvents. The conversion of ascaridole **43** after workup was determined by GC and was 85% at a residence time of only 5 s.

3.3.2.1.2 Photochemical Generation and Addition of Singlet Oxygen to Cyclopentadiene

A further example for the safe conduction of a potentially explosive reaction in a microstructured reactor has been described by Jähnisch and Dingerdissen.⁶⁴ These authors showed that the falling-film microreactor (FFMR by IMM) is also suitable for the continuous photochemical generation of singlet oxygen in the presence of dissolved Rose Bengal. The photooxygenation of cyclopentadiene **44** by singlet oxygen, followed by the reduction to 2-cyclopenten-1,4-diol **46**, has been chosen as a model reaction (Scheme 3.17). The initially generated endoperoxide **45** is potentially explosive, which represents a safety concern for the large-scale conventional synthesis.

SCHEME 3.16 Photoaddition of singlet oxygen to α -terpinene.

SCHEME 3.17 Photoaddition of singlet oxygen to cyclopentadiene and subsequent reduction.

SCHEME 3.18 Sensitized photooxygenation of (S)-(-)- β -citronellol.

The photooxygenation step of this transformation took place in the reaction plate of the falling-film microreactor, which had 32 parallel microchannels of 66 mm length, 600 μm width, and 300 μm depth. A methanol solution of cyclopentadiene was pumped through the microreactor at a flow rate of 1 mL/min, thus creating a very thin layer of liquid. The reactor was additionally cooled to 10°C–15°C. The effluent containing the endoperoxide **45** was passed into a solution of thiourea in methanol at 10°C. The aforementioned techniques and short holdup insured that the quantity of the endoperoxide and the oxygenated solution was always kept at a safe level. As light source, a xenon lamp (1000 W) was used. The oxygen was fed to the reactor counter currently to the liquid with a flow rate of 15 L h⁻¹. Under nonoptimized conditions, the desired product 2-cyclopenten-1,4-diol **46** was obtained in a yield of 20% (0.95 g). This study proved that a falling-film microreactor is suitable for photooxygenation reactions on a preparative scale.

3.3.2.1.3 Photosensitized Oxidation of Citronellol

The photochemical oxidation of (S)-(-)- β -citronellol **47** is used in the fragrance industry to produce (-)-rose oxide.^{65,66} The Schenck-ene reaction of **47** with singlet oxygen yields a mixture of the peroxides **48** and **49** (Scheme 3.18). This transformation was selected by Meyer and coworkers as a model reaction for a reactor comparison study based on space–time yields (STY) and photonic efficiencies.⁶⁷

The microscale oxidation of **47** was carried out in a commercially available microstructured reactor (Little Things Factory GmbH) that was made of HT-residence glass and consisted of a single half-round serpentine channel with a width of 1 mm, depth of 0.5 mm, and a total volume of 270 μL . The reaction mixture was saturated with compressed air in a double-wall storage container outside the microreactor and was continuously pumped through the microreactor in a loop. The illumination took place for about 60–70 h using an LED array (4 \times 10 LEDs, λ_{max} = 468 nm) with light intensities from 1 to 7.98 mW/cm². The batch experiments were performed in the modified Schlenk-tube reactor with an illuminated volume of 7.46 mL (total volume 40 mL). A LED-stick (2 \times 15 LEDs, λ_{max} = 468 nm) with a light intensity of 6.5 mW/cm² was placed at the center of this reactor. Prior to irradiation for 5–8 h, the ethanol solution of (-)- β -citronellol was purged with compressed air for 20 min. The progress of the reaction was monitored by HPLC. The photonic efficiency for the LTF-microreactor was 0.048, which was two times higher than for the Schlenk reactor. Likewise, the STY was about one order of magnitude higher in a microreactor than in a Schlenk reactor. In contrast to the industrial process, a ruthenium complex (tris(4,4'-*tert*-butyl-2,2'-dipyridyl)-ruthenium(II)-dichloride) was used as photosensitizer. While the ruthenium complex has a higher photostability and quantum yields of singlet oxygen formation compared to Rose Bengal, a sensitizer comparison study with 450 W xenon lamp (λ = 50–1600 nm) showed that Rose Bengal is about twice as efficient as the ruthenium complex.

3.3.2.2 Photochlorination Reaction

The portfolio of heterogeneous reactions is not limited to photooxygenations.^{35,68,69} The selective photochlorination of toluene-2,4-diisocyanate **50** (TDI, Scheme 3.19) was examined by Jähnisch et al. in a falling-film reactor (IMM).⁶⁸ The main product of this transformation, 1-chloromethyl-2,4-diisocyanatobenzene **51** (1Cl-TDI), is used industrially as an intermediate in the synthesis of polyurethanes.³⁰

SCHEME 3.20 Photocatalytic synthesis of L-pipecolic acid.

3.3.3.1 Photocatalytic Synthesis of L-Pipecolic Acid

The first application of a photocatalytic microsystem in organic synthesis has been reported by Takei et al.⁸⁰ The authors studied the photocatalytic synthesis of L-pipecolic acid **54** (L-PCA) from L-lysine **53** (Scheme 3.20) in a home-made microchip. The titania-modified microchannel chip (TMC) used in this study was composed of two Pyrex glass substrates. One substrate with branched channels of 700 μm wide and 3.5 μm deep was fused to another substrate with a 300 nm thick coating of TiO_2 . The TiO_2 coating served as catalyst and was made of particles with a diameter of 100 nm. The film contained platinum as reducing agent at 0.2 wt%. A high-pressure mercury lamp with a UV transmitting filter was used for irradiations.

A 2 mM aqueous solution of L-lysine was pumped through the microchip at different flow rates. The crude product mixture was collected from the reactor outlet and was analyzed by HPLC. The results were compared to a batch system comprising a bulk cuvette and TiO_2 particles (diameter 25 nm) in suspension. It is notable that the ratio of illuminated surface area to the solution volume was comparable in both setups (0.29 m^2/mL for the TMC and 0.25 m^2/mL for suspended particles). The conversion of L-lysine **53** to L-pipecolic acid **54** in the microchip reached 87% after a residence time of less than 1 min (0.86 min). In the batch experiment the same conversion rate of 86% was achieved only after 1 h. Analysis of selectivity and enantiomeric excess (e.e.) revealed that these parameters were independent of reaction time and were similar in the micro- and bulk setup (selectivity was 22% and e.e. was 50% and 47%).

In contrast, the productivity for L-PCA **54**, that is, the amount produced per minute, was much lower in the microchip (2.8×10^{-10} mol/min) compared to the bulk system (1.9×10^{-8} mol/min). This was due to the larger volume of the batch cuvette (4 mL), but this disadvantage may be overcome through numbering up of microreactors in the future. A significant advantage of the catalytic microstructured reactor is the exclusion of the separation step, as the immobilized photocatalyst remains in the microchannel while the product is eluted.

3.3.3.2 Photocatalytic N-Alkylation of Amines

Synthetic photocatalysis in microstructured reactors has been intensively studied by Matsushita and Ichimura et al.^{72,81} In their work they used not only miniaturized reactors but also miniaturized light source such as UV-LED arrays. A remarkable example was the TiO_2 -catalyzed N-ethylation of benzylamine **55** (Scheme 3.21).

This reaction was studied in three house-made quartz microreactors with specific illuminated surface areas per unit of volume of 7.3×10^3 , 6.0×10^3 , and $4.0 \times 10^3 \text{ m}^2/\text{m}^3$, respectively. These large areas

SCHEME 3.21 N-ethylation of benzylamine.

were realized in reactor channels with a width of 500 μm , length of 40 mm, and depth of 300, 500, or 1000 μm , respectively. The sides and bottom of the channels were coated with TiO_2 catalyst (Pt-loaded and Pt-free). A 1 mM alcohol solution of benzylamine **55** was fed into the microreactors at a flow rate between 2 and 40 $\mu\text{L}/\text{min}$ and was irradiated with an UV-LED array ($\lambda_{\text{max}} = 365 \text{ nm}$) with a total optical power output of 9.8 mW. The product solutions were analyzed by GC or HPLC methods. Benzylamine **55** could be converted in high selectivity to the N-alkylated product **56** in yields of 43% after just 90 s or 85% after 150 s, respectively.

Ethanol was found to be the most suitable solvent for this transformation due to the kinetic stability of its ethoxy radical intermediate. Consequently, ethanol was applied for alkylation reactions of other amines. Aniline and butylamine were tested and gave the corresponding N-ethylated products in yields of 11% and 36%, respectively, after a residence time of 180 s.

The effect of the depth of the microchannel was also examined and showed that the efficiency of N-alkylation was enhanced with decreasing channel depth. This observation was attributed to the increased illuminated surface-to-volume ratio.

Remarkably, this reaction proceeded in the presence of titanium dioxide photocatalyst, even without cocatalyst platinum and yields of up to 98% of N-alkylated product **56** were achieved after 90 s. In contrast to other studies,⁸² N-alkylation did not occur under batch conditions without the presence of platinum. Selectivity was high in the microreactors and no N,N-dialkylated product **57** was obtained in the presence or absence of platinum. This was achieved by the continuous-flow mode and monochromatic irradiation, which prevented the undesired follow-up reaction. In contrast, bis-alkylation is frequently observed under batch conditions.

The authors further expanded their study on the N-alkylation of amines by optimizing the irradiation and flow conditions.⁸³ A novel photocatalytic microreaction system with a microchannel 500 μm wide, 25 μm deep, and 50 mm long was developed. The high surface area of TiO_2/Pt photocatalyst ($4.0 \times 10^3 \text{ m}^2/\text{m}^3$) achieved was irradiated with a more powerful LED array (total optical power output 490 mW). In this microsystem, the alkylation of amines (benzylamine, aniline, and piperidine) proceeded faster compared to the previously described model. For example, N-ethylbenzylamine **56** was obtained in a yield of 62% after 6 s, however, the bis-alkylated product N,N-diethylbenzylamine **57** was also detected in 3.8% yield. The same trend was noticed for aniline. At a shorter residence time (5 s), the formation of the main product **56** increased with increasing light intensity, whereas at a prolonged residence time (60 s), the formation of the tertiary amine **57** enhanced with increasing light intensity. These results clearly demonstrate that the outcome of the reaction (mono- vs. bis-alkylation) can be controlled by precise control of the irradiation and flow conditions.

3.3.3.3 Photocatalytic Reduction in Microreactors

Another example of a synthetically useful transformation has been also reported by Matsushita et al.⁸⁴ The authors examined the photocatalytic reduction of benzaldehyde **58** and nitrotoluene **60** (Scheme 3.22) in microreactors.

SCHEME 3.22 Photocatalytic reduction of (a) benzaldehyde and (b) nitrotoluene.

For this study, photocatalytic quartz microreactors with immobilized photocatalyst were fabricated. These reactors contained a microchannel of 500 μm width, 100 μm depth, and 40 mm length with a total specific illuminated surface area per unit of liquid of approximately $1.4 \times 10^4 \text{ m}^2/\text{m}^3$. The bottom and side walls of the microchannel were coated with a TiO_2 layer. An array of 365 nm UV-LEDs with an optical power output of 1.4 mW was employed as a light source.

Alcoholic solutions of benzaldehyde **58** (0.1 mM) saturated with nitrogen were used. Ethanol was found to be the most efficient solvent and gave a yield of benzyl alcohol **59** of 11% after 60 s. Photoreduction of *p*-nitrotoluene **60** gave *p*-toluidine **61** in yields of 46% after 60 s. Although the reactions were not further optimized, they demonstrated that microstructured reactor can be utilized for the efficient reduction of organic compounds.

3.3.4 Microphotochemistry in Industry

The reactions described earlier have been performed on laboratory scales. However, isolated examples of gram-scale synthesis have been achieved.^{42,43,51} In contrast, photochemical processes realized on industrial scale are still rare. There are several contributing factors for this neglect. Microreactors are generally made from expensive materials, such as stainless steel or quartz glass. The fabrication of reactor microchannels is also costly and complicated. Despite the increased utilization of energy-efficient LEDs as light sources for photochemical reactions, medium- and high-pressure mercury lamps are still predominantly used in industry. These conventional lamps are costly to run, have a limited lifetime, and additionally tend to generate a large amount of heat and therefore require additional cooling systems. In contrast, product synthesis in kilograms quantity using microreactor clusters requires complex automation and control devices.

Nevertheless, the proven advantages of photochemical synthesis in microreactors make it an interesting synthesis tool for low-volume processes.

3.3.4.1 Synthesis of 10-Hydroxycamptothecin and 7-Alkyl-10-Hydroxycamptothecin

The first industrial production of camptothecin derivatives using a microphotoreactor plant was realized by Heraeus.⁸⁵ The synthesis of 10-hydroxycamptothecin **63a** and 7-ethyl-10-hydroxycamptothecin **63b** from camptothecin-*N*-oxide **62a** or 7-ethyl camptothecin-*N*-oxide **62b** (Scheme 3.23) was performed in this plant. Compounds **63a** and **63b** are precursors in the synthesis of the anticancer drugs irinotecan and topotecan.

The developed plant consisted of twelve microreactors operated in parallel and irradiated by individual light sources (Figure 3.4). The microreactors themselves are characterized by their simple design. They comprise of two parallel quartz glass separated by a spacer, which creates a gap from 40 to 100 μm . The design produces a very thin film of the reaction solution. As light source, mercury high-pressure emitters (Heraeus Noblelight) with a UV emission wavelength range from 350 to 400 nm and an optical power output of 250 W were used. These lamps also comprised spectral filters with a specific band pass and coating on both sides.

The productivity of the microreactor plant was evaluated using the amount of 10-hydroxycamptothecin **63a** produced within 24 h. At conversion rate of 95% of **62a**, the desired product **63a** is produced in

SCHEME 3.23 Synthesis of camptothecin derivatives.

FIGURE 3.4 (See color insert.) Photochemical production plant. (Courtesy of Heraeus.)

an amount of 2 kg/day (yield 90%). In contrast, the batch system reached a maximum conversion of only 85% and a much lower product yield of 50%. Moreover, the concentration of the camptothecin-*N*-oxide solution used in the microsystem (0.6 wt%) was six times higher than in the batch system (0.1 wt%).

This remarkable process represents the first example of a photochemical production in a microreactor array.

3.4 Concluding Remarks

The examples presented in this chapter clearly demonstrate the versatility and potential of microphotochemistry as a synthesis tool. Microstructured reactors have been successfully used for a broad range of photochemical reaction types. The technology takes full advantage of the small dimensions and flow condition of microtechnology. This results in the reduction or complete elimination of side reactions, enhanced selectivity, increased photonic efficiency, and reduction of hazards and wastes. The large area-to-volume ratio within the microchannels is especially advantageous for photocatalytic applications. It is hoped that microphotochemistry will emerge as an important future R&D tool, for example in modern lead development processes, and ultimately as a production technology. The Heraeus process clearly demonstrates this potential. Consequently, microphotochemistry may emerge as “the new photochemistry of the future.” This statement refers to Giacomo Ciamician’s visionary lecture, presented before the International Congress of Applied Chemistry in New York in 1912.⁸⁶

Acknowledgments

Financial support for our work on microphotochemistry was provided by Science Foundation Ireland (SFI, 07/RFP/CHEF817), the Environmental Protection Agency (EPA, 2008-ET-MS-2-S2), and the Department of Environment, Heritage and Local Government (DEHLG, 2008-S-ET-2). We also thank Dr. Thomas Dietrich (mikroglas chemtech), Prof. André Braun (Quantapplied), Günther Peschl (UV-Consulting Peschl), and Dr. Silvia Werner (Heraeus) for useful discussions and support.

4.1 Introduction

It is well known that, for the time being, certain functional groups need a temporary inactivation of their intrinsic chemical properties in order to allow transformations elsewhere in a molecule. This inactivation is achieved by protecting groups, the use of which has been frequently reviewed, commented, and criticized.^{1,2} When the original reactivity of a functional group has to be restored, the protecting group needs to be removed by a reagent, which should be strong enough to induce the detachment of the protecting moiety, but mild enough to keep the rest of the molecule intact—including possibly other protecting groups that must be maintained for further transformations. This compatibility between different protecting groups, that is, the possibility of their selective removal in any given sequence, is often called *orthogonality*, and this is highly desirable in order to give to the synthetic plan a certain flexibility. However, the number of orthogonal sets of hydrolysis conditions is unfortunately rather small (e.g., acidic, basic, reductive, oxidizing, and nucleophilic conditions), and thus any additional dimension would be welcome.

In this context, light is an interesting “reagent,” as only a few functional groups are photosensitive (at reasonable intensities and photon energies). Therefore, the availability of protecting groups that can be removed by mild irradiation (say, for a few minutes at wavelengths between 300 and 450 nm) might help to solve various synthetic problems. Such photolabile protecting groups (PPGs) do indeed exist, and a certain degree of orthogonality between them, exploiting different excitation wavelengths, has been demonstrated (*chromatic orthogonality*).^{3–6}

The field of PPGs has been reviewed by many on several occasions,^{7–13} including us.^{14,15} Some of these reviews were either focused on certain applications or grouped according to their mechanisms. In this

chapter, in order to give the reader a useful overview on what can be achieved using PPGs and to help the synthetic chemist to choose the appropriate one, we decided to sort them according to the type of functional groups that can be protected, with only a brief listing of the main families. Later consultation of more focalized articles is nevertheless advised.

4.2 Main Families of PPGs

A very large number of different PPGs have been developed since the initial work published by Barltrop and Schofield in 1962,^{16–18} and soon after by Barton et al.^{19,20} but they are frequently variations of a common core structure. The main families are listed hereafter.

4.2.1 *o*-Nitrobenzyl Derivatives

These compounds are by far the most popular PPGs, since their early application by Patchornik, Amit, and Woodward in 1970.²¹ They are based on the abstraction of a benzylic hydrogen by a neighboring excited nitro group, followed by a cascade of reactions that lead eventually to the release of the Y group (Scheme 4.1). This family of PPGs is quite versatile, as Y can range from an alcohol to a carboxylic acid, an amine, an amide, a phosphate, and even a masked carbonyl group.

4.2.2 Benzyl Alcohol Derivatives

A benzylic carbon–Y bond (Y being frequently an oxygen-bound moiety) has been shown to undergo photolytic cleavage,²² possibly by heterolysis, as the benzylic carbocation is stabilized in the excited state (the *meta* effect), although this mechanism has been disputed.^{23,24} Various substituents on the aromatic ring, in particular methoxy groups at both *meta* positions, greatly accelerate the reaction (Scheme 4.2). Diverse variations on the aromatic part itself have also been proposed, such as polyaromatics or heterocycles (*vide infra*).

4.2.3 Norrish Type II

Similar to the *ortho*-nitrobenzyl-based PPGs, the abstraction of a benzylic hydrogen atom by a nearby excited carbonyl group (i.e., a Norrish-type II reaction) has been exploited (Scheme 4.3).²⁵ It is worth noting that, in some cases, the released group has an oxidation state higher than before irradiation. This has to be taken into account in the synthetic planning:

SCHEME 4.1 Photolysis of *o*-nitrobenzyl derivatives.

SCHEME 4.2 Photolysis of benzyl alcohol derivatives.

SCHEME 4.3 Photolysis of PPGs by a Norrish-type II mechanism.

SCHEME 4.4 Photolysis of PPGs by a Norrish-type I mechanism.

4.2.4 Norrish Type I

A completely different approach is used on pivaloyl derivatives, where the photoinduced homolysis of the C–C bond adjacent to a carbonyl group (Norrish-type I reaction) is followed by a cascade of reactions leading to the liberation of a carboxylic acid (Scheme 4.4).^{26–28}

4.2.5 Cinnamyl Esters

Cis–trans isomerization of alkenes is a common photochemical reaction, and it was exploited in cinnamate esters, where photoisomerization to the *Z*-isomer allowed an intramolecular transesterification, which leads to the release of an alcohol (Scheme 4.5).^{29,30}

4.2.6 Coumarin Derivatives

The coumarin chromophores, released as side products in the photolysis of cinnamyl esters (see Section 4.2.5), have also been employed to protect a broad variety of functional groups (Scheme 4.6).^{31–34} The postulated mechanism involves a heterolytic cleavage of the C–Y, leading to the formation of an ion pair.³⁵

SCHEME 4.5 Photolysis of (*E*)-cinnamyl esters.

SCHEME 4.6 Photolysis of coumarin derivatives.

Low-energy irradiation (>320 nm or two-photon absorption), solubility in aqueous media, and nontoxicity of coumarin derivatives have made them ideal candidates for “caging compounds” despite their relatively low quantum yields.¹⁰

4.2.7 Phenacyl Derivatives

Phenacyl groups containing a leaving group in the α -position can be efficiently photolyzed, particularly if a *para*-hydroxy group is present on the aromatic ring.^{36–46} The exact mechanism can vary depending on the particular substituents; either a radical pair or an intramolecular S_N2 attack by the *ipso* carbon atom is involved (Scheme 4.7).

A related core structure was recently developed by Klan et al. for the protection of a wide variety of functional groups. However, despite the structural similarities, the mechanism follows different pathways, depending on the nature of the solvent in which the photolysis is conducted (Scheme 4.8).^{47–52}

4.2.8 Benzoin Derivatives

Structurally close compounds, benzoin esters, with an additional aromatic group α to the carbonyl group also react very efficiently upon irradiation. However, the mechanism follows a different path, as benzofuran derivatives are the common side products. Again several routes have been proposed, involving a radical cyclization, an intramolecular Paterno–Büchi [2 + 2] cycloaddition or a cationic intermediate (Scheme 4.9).^{53–61}

4.2.9 7-Nitroindolines

Acylated 7-nitroindolines smoothly transfer the acyl group to an incoming nucleophile upon irradiation, and this feature has been exploited in a series of PPGs (Scheme 4.10).^{62–70} The photolysis mechanism involves the photoinduced migration of the *N*-acyl group to one of the oxygen atoms from the nitro group, generating a very electrophilic *O*-acyl intermediate, then trapped by the nucleophile. Time-resolved infrared spectroscopic studies confirmed this mechanism.⁷¹

SCHEME 4.10 Photolysis of 7-nitroindoline derivatives.

4.3 PPGs for Specific Functional Groups

4.3.1 PPGs for Carboxylic Acids

Carboxylic acids are probably the most easily protected groups, as esters of most photoreactive alcohols can be used. Very common are *ortho*-nitrobenzyl alcohol esters such as **1**, which can be prepared by simple esterification procedures (e.g., DCC-type coupling). Among the multitude of example, the following is interesting, because the released carboxylic acid is itself strongly absorbing, but without significant detrimental interference (Scheme 4.11).⁷²

ortho-Nitroanilides such as **2** are interesting (Scheme 4.12), because their photolysis in water-containing media lead to carboxylic acids,⁷⁰ whereas in amine-containing media it leads to amides (ammonia furnishes carboxamides, but—more interestingly—aminoacids lead to dipeptides).^{62,73} In methanol, a methyl ester is obtained, and a stoichiometric amount of a large variety of alcohols (even tertiary) in anhydrous acetonitrile leads to esters.⁷⁴ It is thus a very versatile PPG, despite its relatively difficult acylation, which requires acid chlorides activated by aluminum trichloride; otherwise, acylation of indoline, followed by nitration is required. If these harsh conditions are incompatible with sensitive parts on the carboxylic side, an indirect route is necessary.^{68,75}

Very efficient release is observed in the photolysis of benzoin esters, with a relatively harmless by-product (a benzofuran derivative).^{53,54,57,61} A combination of benzoin esters (sensitive to short wavelength) and *ortho*-nitrobenzyl esters (sensitive to longer wavelength) was used in the initial

SCHEME 4.11 Release of carboxylic acids from *o*-nitrobenzyl esters.

SCHEME 4.12 Release of carboxylic acids from 7-nitroindoline amides.

SCHEME 4.13 Example of chromatic orthogonality.

SCHEME 4.14 Release of carboxylic acids from phenacyl esters.

description of chromatic orthogonality (**3**, Scheme 4.13).^{4,6,76} Despite their very high photolysis quantum and chemical yields, benzoin esters suffer from a relatively high sensitivity to common organic reagents (e.g., hydrides or most organometallic reagents) and sometimes from difficulties in making the esters themselves (benzoin is prone to α -ketol rearrangement).

Also suffering from significant sensitivity toward common organic reagents, phenacyl esters **4** remain interesting candidates for specific applications, particularly in biochemistry (Scheme 4.14).³⁷

The Norrish-type I fragmentation of pivaloyl derivatives has been introduced as part of a photolabile linker, but it proceeds as well for conventional solution-phase chemistry (**5**, Scheme 4.15).²⁸ Despite the presence of a carbonyl group, pivaloyl esters show remarkable stability toward a series of chemical conditions (such as acids, bases, or transition-metal catalysis). The by-products are gaseous or volatile molecules (isobutene, carbon monoxide, and acetone), and the photolysis quantum yield is very high; on the other hand, it requires irradiation with a relatively short wavelength (280–340 nm).

4.3.2 PPGs for Amines

Historically, amines were among the first functional groups for which PPGs were developed, as part of a strategy for peptide synthesis.^{11,77} The nitrogen atom is protected as a carbamate, which is conveniently formed by the reaction of the free amine with the corresponding photolabile chloroformate. The most common PPGs are variations of the *ortho*-nitrobenzyl motif (**7**, Scheme 4.16), such as

SCHEME 4.15 Traceless release of carboxylic acids.

SCHEME 4.16 Example of *o*-nitrobenzyl derivatives of amino acids.

4,5-dimethoxy-2-nitrobenzyl carbamates **6** (nitroveratryloxycarbonyl, or NVOC). The two methoxy groups were introduced to shift the irradiation to longer wavelengths (up to 420 nm), as deep UV light can be harmful to some amino acids (such as tryptophan) or nucleic acids. This redshift occurs at the cost of a decrease in quantum yield, but unless very specific performances are expected, this has no practical consequences. An improved version was introduced a decade ago, by adding an additional methyl group at the benzylic position and a methylenedioxy group on the aromatic ring (**8**). This group, called MeNPOC, is photolyzed more efficiently than its unsubstituted NBOC counterpart **7**, also at longer wavelengths, but it is not widely accessible commercially, and an enantiopure version is essential to avoid the formation of diastereomeric pairs with chiral compounds.^{78,79}

A related PPG bearing a nitrodibenzofuran core was recently introduced. Interestingly, it shows a high two-photon cross section, thus allowing deprotection at wavelengths as long as 710 nm, using a focused laser beam (**9**, Scheme 4.17).^{80,81}

A significant drawback of such PPGs is the release of a dark-colored nitroso side product, which progressively limits the light availability over time, and which needs to be separated from the released product. Cleaner, but also requiring a purification step, are derivatives of the simple 3,5-dimethoxybenzyl alcohol, such as carbamate **10**; on the other hand, shorter wavelengths are required, and compatibility tests should be performed before including such PPGs in longer syntheses.²² An improved version includes two methyl groups at the benzylic site (Ddz, **11**).⁸² Interestingly, the α -methyl styrene side product undergoes a [2 + 2] cyclodimerization, but this process is normally not detrimental to the overall reaction (Scheme 4.18). Ddz derivatives are, however, very acid sensitive, about three orders of

SCHEME 4.17 Example of a nitrodibenzofuran derivative of thymidine phosphoramidite.

SCHEME 4.18 Release of amino acids from benzyl alcohol derivatives.

SCHEME 4.19 Release of amines from *o*-methylated phenacyl derivatives.

magnitude more than the Boc group. It is also worth noting that the cleavage of the 3,5-dimethoxybenzyloxycarbonyl group requires water to proceed (the reaction is a solvolysis), whereas the Ddz variant can be cleaved in anhydrous media.

Variations of the phenacyl group can be used in carbamates (**12**) to protect amino groups, and the photodeprotection proceeds in high yields. Interestingly, in nucleophilic solvents such as methanol, the release mechanism does not follow the usual route for phenacyl groups, but rather proceeds through a photoenol (Scheme 4.19).⁵²

4.3.3 PPGs for Alcohols

There are numerous ways to protect alcohols with PPGs, as ethers, carbonates, and mixed acetals. It should however be pointed out that, although simple by principle, this sort of protection can pose certain synthetic problems, as the formation of such derivatives is sometimes cumbersome to optimize.

Although formally part of a carbonyl group, but more alcoholic from the reactivity point of view, the anomeric hydroxyl group of sugars has been protected as a mixed acetal with a nitrobenzyl alcohol derivative in the early days of PPGs. For example, the derivatives of glucose **13** in Scheme 4.20 were photolyzed in a 100% yield.⁸³ This strategy is also compatible with more complex structures, such as a precursor for Aplysiatoxin (**14**, Scheme 4.20).⁸⁴

Another very important field where PPGs are used is in the light-directed automated synthesis of oligonucleic acids or peptides (Scheme 4.21).^{85,86}

A structurally related group, the 2-(2-nitrophenyl)propyloxycarbonyl (NPPOC), has been shown to be quite efficient in releasing alcohols upon irradiation.^{87–93} Despite the similarity, the reaction proceeds by a photoelimination (Scheme 4.22). For example, cytosine derivative **15** or thymine derivative **16** was deprotected almost quantitatively.

The benzylic photosolvolysis that we cited in the introduction has been widely used with a series of variations (Scheme 4.23), such as the Pixyl derivative **17** and its *S*-Pixyl analogue **18**,^{94–96} the Aqmoc **19**, Pmoc **20**, Phmoc **21**, and Mcmoc **22**.⁹⁷ The naphthalene derivative **23**, although also bearing a benzylic leaving group, apparently reacts via a different mechanism, as a quinone methide intermediate was observed.^{98,99} The Bhc derivative **24** and the BHQ derivative **25** are promising candidates for biological applications, as they exhibit significant two-photon absorptions.^{100–103}

A convenient family of PPGs, by virtue of the ease of their preparation, is the hydroxycinnamyl derivatives, such as ester **26**. Irradiation triggers the isomerization of the *trans*-olefin to its *cis*-isomer, which

SCHEME 4.20 Release of alcohols from *o*-nitrobenzyl derivatives.

SCHEME 4.24 Release of alcohols from (*E*)-cinnamyl esters.

can undergo an intramolecular transesterification, thus liberating the alcohol (Scheme 4.24). However, with regard to robustness, the numerous chemically sensitive functions (phenol, olefin, ester) make this group more appropriate for specific uses where *release* is more important than *protection*, as it can be the case in biochemistry or particular technologies (e.g., fragrance release).^{29,104–109}

Glycols can be protected as ketals and photochemically released, as illustrated by a salicylaldehyde derivative (27, Scheme 4.25).¹¹⁰

SCHEME 4.25 Release of diols.

SCHEME 4.26 Release of ketones.

4.3.4 PPGs for Carbonyl Groups

The most commonly used strategy to mask a carbonyl group is to convert it into an acetal or ketal. Variants of the *ortho*-nitrobenzylic core have been developed over the years, with derivatives like **28**, **29**, or **30** (Scheme 4.26). **28** was the first of such groups, which was remarkably robust under acidic conditions, but quite labile in basic media.¹¹¹ The homochiral version **29** improved the stability toward bases, and allowed the protection of chiral carbonyl compounds without the formation of diastereomeric pairs.¹¹² Derivative **30** was later introduced for an improved absorption at longer wavelengths (up to 400 nm).¹¹³ A different type of diol (**31**) was recently developed, the ketal of which releases a ketone by an excited state proton transfer, in yields ranging between 59% and 100%.¹¹⁴ The coumarin derivative **32** is particularly interesting for its high two-photon cross section.¹¹⁵

Although it is not strictly speaking a protection, the photoinduced release of a carbonyl compound using a Norrish-type II reaction has been used, in particular for the release of fragrances (e.g., **33** and **34**).^{116–119} It is based on the abstraction of a hydrogen *ipso* to an oxygen atom, making it formally an oxidative process (Scheme 4.27).

A completely different approach exploits the photofragmentation of α -hydroxy-*ortho*-thioesters (**35**). The reaction can be sensitized, thus allowing the use of nonabsorbing substituents and the possibility of working at relatively long wavelengths (Scheme 4.28).^{120–123}

The *meta* effect operating in the photolysis of benzylic esters has been invoked in the development of phenol-derived ketals **36** (Scheme 4.29).^{124,125}

4.3.5 PPGs for Thiols

Thiols can be protected with PPGs, and most of the standard cores have been used, in a similar fashion as for alcohols. As photoliberation of thiols frequently involves biomolecules (e.g., cysteine derivatives), water solubility can be an issue, and various substituents on the cores have been introduced.^{60,126–128} Thiols can be either directly attached to the reacting center, such as in *ortho*-nitrobenzylic derivative **37**, or via a thiocarbonate, such as in **38** (Scheme 4.30).¹²⁹

SCHEME 4.27 Oxidative release of fragrances.

SCHEME 4.28 Photolysis of *o*-thioesters.

SCHEME 4.29 Photolysis of phenol-derived ketals.

SCHEME 4.30 Examples of protected thiols.

SCHEME 4.31 Release of phosphates from *o*-nitrobenzyl derivatives.SCHEME 4.32 Release of phosphates from *p*-hydroxyphenacyl derivatives.

4.3.6 PPGs for Phosphates

In an early example, the phosphate group of a nucleotide was protected by an *ortho*-nitrobenzylic group (**39**, Scheme 4.31).¹³⁰ Shortly thereafter, ATP was protected (**40**) and photochemically released.¹³¹

Phenacyl phosphate esters release phosphates upon irradiation very efficiently, in particular derivatives bearing a *para*-hydroxy group (**41**, Scheme 4.32).¹³² The key feature of this group is the very high release rate, crucial in several biochemical applications. An additional interesting feature is the lower absorbance of the nonconjugated *para*-hydroxy-phenylacetic by-product (avoiding the darkening of NVOC-type irradiated solutions, as mentioned earlier), which does not interfere in the photolytic process.

4.4 Conclusion

Other types of functional groups can of course be protected and later photochemically released; many of the specific applications are derived from the larger families presented in this overview. Apart from that, there are a series of very ingenious, though specific, methods, such as the protection/photodeprotection of the silyl group.^{133–135} At the moment, there are few uses for this kind of PPG in general organic synthesis, but its mere availability might orient choices in a future synthetic scheme or technological development.

This book shows the breadth of reactions promoted by light, as well as their sometimes discouraging sensitivity to substituents and experimental conditions. The photolysis of PPGs are, however, part of a privileged class of reactions, which are quite tolerant to different reaction conditions and structural patterns, provided that the core motifs adhere to the general reactivity of the groups seen in Section 4.2, and that the incident light wavelengths coincide at least partially with those of the relevant chromophore's absorptions. This tolerance might actually be the reason why PPGs find increasing uses in a wide variety of fields, ranging from lithography to biology, material science, or organic synthesis.

5.1 Introduction

Photochemical reactions are characterized by the transformation of electronically excited molecules that are generated by light absorption.^{1,2} Compared to their ground state, such excited molecules possess completely different electronic configurations. Consequently, their chemical reactivity completely changes. Frequently, complementary reactions are observed for molecules at the ground and the excited states.³ Thus, using photochemical reactions, the spectrum of chemical transformations of a compound family is significantly enlarged. Total syntheses can be shortened, and frequently complex, polycyclic, or highly functionalized structures can easily be obtained from simple substrates.⁴ New product families or product libraries difficult to achieve with ground-state reactions are thus available, opening new perspectives in the search of biologically active compounds. Catalytic reactions are also affected by light irradiation. Either ground-state reactions become more efficient or new catalytic reactions are observed. Such reactions also enrich the methodology in organic synthesis. After a period of stagnation, activity in the field of organic photochemical reactions and their application to synthesis has started to grow again in academic and industrial research. In the two preceding editions of this handbook⁵ as well as in other books,^{1,6,7} large collections of organic photochemical reactions are presented. Many books deal with experimental conditions and equipment.^{1,8} This chapter briefly discusses some selected examples predominantly chosen in the field of total synthesis and synthesis of biologically active compounds. The examples have been mainly taken from recent literature.

5.2 Photocycloadditions

5.2.1 [2 + 2] Photocycloadditions

Among the photochemical reactions, the [2 + 2] photocycloaddition of α,β -unsaturated carbonyl compounds with alkenes, allenes, or alkynes leading to cyclobutanes or cyclobutenes, respectively,⁹ is certainly the most applied reaction in organic synthesis.^{10,11} The reaction can be performed either by using direct excitation of the α,β -unsaturated carbonyl chromophore or by sensitization. In the latter case, acetone is most frequently used as sensitizer to transform α,β -unsaturated carboxylic compounds. Acetone absorbs light and after intersystem crossing, the triplet energy is transferred onto the substrate. The intramolecular version of these reactions was frequently applied to complex multistep syntheses of natural products. In such a reaction, the bisfuranone compound **1** is transformed into the cyclobutane derivative **2** (Scheme 5.1, Equation 5.1).¹² Principally, the [2 + 2] photocycloaddition can take place at both furanone moieties. Obviously, only excitation of the less conjugated and thus more reactive furanone leads to cycloaddition. Although 1,4-biradical intermediates are involved in these reactions, the

SCHEME 5.1 Intramolecular [2 + 2] photocycloaddition of α,β -unsaturated carbonyl compounds.

transformation is highly stereoselective.⁹ Particularly in intermolecular reactions, these intermediates often diminish the stereo- and regioselectivity.¹³ Compound **2** is a partial structure of the diterpene, bielschowskyisin, which is isolated from corals *Pseudopterogorgia kallos*. Bielschowskyisin possesses cytotoxic and antiparasitic activities. A similar strategy but using the intramolecular [2 + 2] photocycloaddition of allenes to furanones has been applied to the synthesis of this compound¹⁴ and other natural products.¹⁵

The same acetone sensitized [2 + 2] photocycloaddition was applied to the synthesis of ingenol. The challenge of this synthesis is to build up, in a straightforward way, a bicyclo[4.4.1]undecan-11-one moiety with *trans* junction of the two seven-membered rings. The intramolecular cycloaddition of the tricyclic dioxxygenone derivative **3** yields the cyclobutane derivative **4** possessing already one seven-membered ring (Scheme 5.1, Equation 5.2).¹⁶ The stereochemistry of the *trans* linkage of the bicyclo[4.4.1]undecan-11-one system is established in this step. It is controlled by the presence of the chlorine atom in the allylic position of the alkene side chain of **3**. Elimination of the isopropylidene group intermediately generates the aldol **I**. A retroaldol reaction leads to the second seven-membered ring of the target. Further in situ transformations lead to compound **5**, which is transformed into the final product ingenol. β -Diketones often exists in equilibrium with a β -hydroxyenone (mono enolized biacetyl chromophore). After [2 + 2] photocycloaddition with an alkene, the resulting aldole undergoes retroaldol cleavage.¹⁷ The combination of these two reaction steps is also called de Mayo reaction. The [2 + 2] photocycloaddition in combination with a retro Mannich reaction was also applied to synthesis.¹⁸

The intramolecular transformation of the cyclopentenone derivative **6** is induced by direct excitation (Scheme 5.1, Equation 5.3).¹⁹ The enone moiety is added to a furan ring leading to the cyclobutane derivative **7**, which is obtained in quantitative yield. It should also be pointed out that the reaction is completely stereoselective. Electronic effects such as the electron-rich olefinic partner and the substitution at the linking group (allylic 1,3-strain²⁰) contributes to the efficiency of the reaction. Compound **7** was transformed into ginkgolide B1. Derivative **7** possesses already significant structural elements of the target.

Chiral induction in photochemical reactions is extensively studied also with the aim to apply such transformations to organic synthesis.^{21,22} Frequently, the intermolecular version of the reaction is less stereoselective.²³ Nevertheless, if the resulting stereoisomers can easily be separated, such transformations become interesting for application in organic synthesis. The acetone-sensitized transformation compound **8** obtained from uracil with ethylene yields a mixture of diastereoisomers **9a,b** (Scheme 5.2, Equation 5.4).²⁴ After chromatographic separation, the isomers were transformed into the cyclobutane amino acids **10** and *ent*-**10**, respectively. Cyclobutane amino acids possessing an additional hydroxymethyl group are also available in a similar way.²⁵ These are β -amino acids that significantly affect secondary and tertiary structures when incorporated in polypeptides.²⁶ Thus the rigidity caused by the cyclobutane ring may favor the formation of a helix structure. The same kind of reaction was also applied to several cyclobutane containing natural products.²⁷

Using chiral templates^{22,28} such as lactame **13** derived from Kemp's acid, the intramolecular reaction of quinolone **11** with olefine **12** is performed in high yield and complete dia and regioselectivity (Scheme 5.2, Equation 5.5).²⁹ In the template structure, the two lactame functions of **13** and **11** are linked together via hydrogen bonds. Such catalysts can also be considered as organocatalysts.³⁰ Under basic reaction conditions, a rearrangement (**II**) takes place leading to the tricyclic compound **15**. This compound was further transformed into the alkaloid (+)-meloscine.

[2 + 2] Photocycloaddition between two alkenes is catalyzed by Cu(I) salts.³¹ This reaction was frequently applied to the synthesis of natural products possessing a cyclobutane ring. When the enolether **16** was irradiated in the presence of a copper (I) salt, the cyclobutane derivative **17** was obtained in high yields (Scheme 5.3).³² The high stereoselectivity of the transformation is explained by the complexation of both olefin moieties by a copper ion. Compound **17** was transformed into (–)-grandisol, which is a component of the aggregation pheromone of the male boll weevil (*Anthonomus grandis*). This product was frequently synthesized using photochemical reactions as key steps.³³

SCHEME 5.2 Intermolecular [2+2] photocycloaddition of α,β -unsaturated carbonyl compounds.

SCHEME 5.3 Intramolecular Cu(I)-catalyzed [2+2] photocycloaddition of alkenes.

Small heterocycles such as oxetanes can also be obtained via [2+2] photocycloaddition. Electronically excited carbonyl compounds react with alkenes (Paternò-Büchi reaction).^{11,34} Many investigations have been carried out on various stereochemical aspects of this reaction.³⁵ The transformation of dihydropyrrole **18** with benzaldehyde yielded the two diastereomeric oxetanes **19a,b** (Scheme 5.4).³⁶ It should be indicated that the reaction is stereospecific as far as the relative configuration of the three chiral centers

SCHEME 5.4 Paternò-Büchi reaction of benzaldehyde with the dihydropyrrole derivative **18**.

in the oxetane ring is concerned. Only the *syn*-isomer is formed.³⁷ The two diastereomers isolated from the reaction mixture resulted from the induction of the chiral center at the position of the *n*-nonyl substituent. The major isomer **19a** was transformed into the pyrrolidine alkaloid (+)-preussin.

5.2.2 Photocycloadditions of Higher Order

In accordance with the Woodward–Hoffmann rules³⁸ and for concerted reactions, photochemical excitation induces a reactivity that is complementary to that at the ground state. Thus, [4 + 4] cycloadditions can be easily carried out under photochemical conditions.³⁹ Intermediates such as biradicals are also frequently involved in higher order cycloadditions. An example is depicted in Scheme 5.5.⁴⁰ Irradiation of the maleimide derivative **20** leads to the formation of the biradical **IV**.⁴¹ Intramolecular addition yielded the tetracyclic compound **21**. This step is a formal [5 + 2] cycloaddition. It should be mentioned that product **21** is also photoreactive, which diminishes the yield of the reaction. However, when the transformation is carried out in a “high flow-rate/low volume continuous photochemical FEP reactor,”⁴² the yield can be considerably increased. This technique also allows large-scale transformations and can be considered for industrial applications. Further transformations of **21** led to (±)-neostenine, which belongs to the family of *Stemona* alkaloids.

SCHEME 5.5 Intramolecular formal [5 + 2] photocycloaddition of a maleimide moiety with an alkene.

Generally, singlet excited states are highly polarized. In the case of tautomeric equilibria, the formation of the more polar one is favored at the excited state, which is in contrast to the ground-state reactivity. Upon irradiation, hydroxyflavone **22** yields intermediately the oxidopyrillium ion **V**, which, in the presence of an excess of methyl cinnamate **23**, is trapped by a [2 + 3] cycloaddition, leading to compound **24** (Scheme 5.6).⁴³ The intermediate **V** is already localized on the potential energy surface of the ground state. Similar compounds can also be generated with ground-state reactions.⁴⁴ During workup

SCHEME 5.6 [2 + 3] Photocycloaddition of a hydroxyflavone derivative.

and in particular during chromatography on silica gel, **24** is partially transformed into the cyclobutane **25**. The latter compound was not detected in the crude reaction mixture. It does not therefore result from a [2 + 2] photocycloaddition. Basic treatment of the mixture of compounds **24** and **25** yields **26** as a mixture of keto-enol tautomers. After reduction, the diastereoisomers **27a,b** are obtained. The major isomer **27a** was transformed into (–)-silvestrol. During these steps, an optical resolution was performed. An asymmetric synthesis using a TADDOL as chiral template was also described.⁴⁵ Various derivatives of this compound have been synthesized in the same way. It should be pointed out that the photochemical key step is essential in these syntheses since numerous ground-state reactions, in particular 1,4 addition cyclizations to the highly substituted α,β -unsaturated carbonyl system, were unsuccessful. The target compounds are particularly interesting due to their cytotoxic activity.

5.2.3 Photocycloadditions of Aromatic Compounds

Most ground-state reactions of aromatic compounds are characterized by a great tendency to regenerate aromaticity in the products. For instance, electrophilic substitution is certainly the most characteristic transformation of benzene-type aromatic compounds. Photochemical reactions however possess a strong tendency to yield nonaromatic products. Typical examples that have been applied to organic synthesis are photocycloadditions with alkenes.^{46,47} Three modes can be distinguished: [2 + 2] (*ortho*-photocycloaddition), [2 + 3] (*meta*-photocycloaddition), and [2 + 4] (*para*-photocycloaddition or photo-Diels–Alder reaction) (Scheme 5.7). The [2 + 3] photocycloaddition⁴⁸ of benzene derivatives was most frequently applied to organic synthesis.

When irradiated, the benzene derivative **28** yielded a mixture of the angular (**29**) and the linear (**30**) photocycloadduct (Scheme 5.8).⁴⁹ This regioselectivity is not controlled since both isomers were isolated in almost equal proportions.⁴⁷ However, both products **29** and **30** are in photostationary equilibrium so that the desired angular isomer **29** can be prepared in an excess. The transformation is stereospecific. The approach of the olefinic side moiety to the electronically excited benzene ring is controlled by an allylic 1,3-strain effect in the transition state **VI**.²⁰ Only one stereoisomer of the intermediate **VII** is formed. Since the reaction occurs at the singlet state, **VII** possesses zwitterionic character. Charge or radical combination occurs in two ways, leading either to the angular (**29**) or the linear (**30**) compound. Product **29** was transformed into the sesquiterpenoid penifulvin A, which is isolated from the fungus *Penicillium griseofulvum*. It belongs to the structure family of fenestranes⁵⁰ and possesses significant insecticidal activity. The fact that the reaction occurs at the singlet state also avoids *cis/trans* isomerization at the olefinic side chain. Thus the *trans* isomer **31** was transformed into penifulvin B and the *cis* isomer **32** into penifulvin C.⁵¹

The [2 + 2] photocycloaddition frequently occurs in competition to the [2 + 3] one.⁵² Depending on the substituents, one of the two modes is favored. Despite the fact that also in this case, complex polycyclic compounds are obtained starting from simple substrates, few applications to organic synthesis have

SCHEME 5.7 Photocycloadditions of benzene derivatives.

SCHEME 5.8 Intramolecular [2 + 3] photocycloaddition of aromatic compounds.

been described. Recently, such reactions were applied to the synthesis of neurotransmitter analogues⁵³ and to the synthesis of intermediates for the production of herbicides.⁵⁴

5.3 Photochemical Rearrangements

Among the photochemical rearrangements, the oxa-di- π -methane rearrangement has been applied to the synthesis of complex polycyclic natural products. This rearrangement is observed with β,γ -unsaturated carbonyl compounds (Scheme 5.9, Equation 5.6).⁵⁵ Most frequently, the reaction is observed at the triplet state possessing $\pi\pi^*$ character. This means that the transformations can easily be carried out using triplet sensitization. Under these reaction conditions with acetophenone as sensitizer, the tricyclic compound **33** was transformed into compounds **34**, **35**, and **36** (Scheme 5.9, Equation 5.7).⁵⁶ In a second photochemical reaction, the diastereomer **34** is transformed into **35**. Under optimized conditions, the

SCHEME 5.9 Oxa di- π -methane rearrangement.

latter compound can be obtained in high selectivity. Compound **36** presumably results from a 1,3-acyl rearrangement at the singlet state. Under the optimized conditions, this compound is only obtained in traces. Compound **35** was transformed into the triquinane-type natural products (+)-hirsutic acid and (-)-complicatic acid. The latter compound could act as serotonin 5-HT₆ receptor antagonist. This pharmacological activity is interesting in the context of the treatment of Alzheimer disease.

Photodeconjugation of α,β -unsaturated carbonyl and carboxyl compounds is a versatile reaction to modify a functional group.⁵⁷ The transformation was also applied to the synthesis of natural products. Recently, a corresponding diester (**37**) has been transformed (Scheme 5.10, Equation 5.8).⁵⁸ After light absorption, the dienol **VIII** is generated via 1,5-hydrogen shift. Protonation of this intermediate in the presence of an amino alcohol leads to the deconjugated product **38** as mixture of *cis/trans* isomers. These compounds have been transformed into amphiasterin B4 and its epimer **39**. Amphiasterin B4 is isolated from the sponge *Plakortis quasiamphiaster* and possesses cytotoxic activity. The reaction was also applied to asymmetric synthesis. The dienol intermediate can be protonated by a chiral amino alcohol.⁵⁹ Chirality can also be induced by a chiral auxiliary attached as alcohol part of the ester function.⁶⁰

A similar photochemical reaction is observed with benzaldehyde derivatives. Irradiation of compound **40** leads to the intermediate **IX** in which the aromatic character is suppressed (Scheme 5.10, Equation 5.9).⁶¹ As in the previous case, this reaction step can be considered as a 1,5-hydrogen shift. The intermediate is trapped by an intramolecular Diels–Alder reaction. Thus starting from a relatively simple substrate, a complex polycyclic molecule (**41**) is obtained in high yield and complete stereoselectivity.

SCHEME 5.10 Photochemical generation and reactions of dienol intermediates.

The stereochemical course of reaction is explained by an allylic 1,3-strain effect (compare Schemes 5.1 and 5.8, Equation 5.1). A very similar reaction with almost complete chiral induction was carried out in a template structure.⁶² Compound **41** was transformed into 5-*epi*-hamigerane and 5-*epi*-4-bromohamigerane B. Similar examples have been reported.⁶³ In a more general context, the intermediate IX contains a *ortho*-quinodimethane structure. Such structures are generated in many syntheses of polycyclic compounds.⁶⁴

Photochemical cyclization reactions are frequently observed. In particular, many reports exist on application of electrocyclic reactions to organic synthesis.⁶⁵ These reactions occur at the ground and the excited states. The stereochemical course is determined by the Woodward–Hoffmann rules and it is complementary for both electronic states.^{38,65} As far as the application to organic synthesis is concerned, such reactions can also be successfully carried out with highly functionalized substrates. Upon irradiation, compound **42** undergoes photocyclization, leading to the intermediate X in the sense of a 6 π electrocyclization, which involves the polar mesomeric form of the amide function (Scheme 5.11).⁶⁶ This process is certainly favored by the presence of a hydrogen bond from an adjacent phenol to the amide oxygen. Furthermore, an additional substituent on the amide nitrogen is necessary to establish a favorable conformation for the cyclization step. The final product **43** is generated by a 1,5-hydrogen shift. Compound **43** was transformed into (+)-narciclasine and (+)-pancratistatin. These alkaloids have been isolated from the roots of *Pancreatium littorale* and possess antitumor activity. Compared to corresponding ground-state transformations, the photochemical reaction conditions are much milder. Therefore, this kind of photocyclization was applied as a versatile step to the total synthesis of natural products

SCHEME 5.11 Photochemical cyclization of an aromatic enamide.

of various alkaloid families and other biologically active compounds.⁶⁷ Derivatives of narciclasine and pancratistatin have been synthesized in a similar cyclization step but with a photochemical electron transfer as key step (see the following).⁶⁸

5.4 Photochemical Electron Transfer–Mediated Transformations

Electron transfer–mediated reactions play also an important role in organic synthesis. At the ground state, electron transfer is controlled by the redox potentials of the substrate molecules and the redox reaction is only possible when the LUMO of the acceptor molecule is energetically lower than the HOMO of the donor molecule. Due to electronic excitation by light absorption, the redox potential changes and the exothermicity of photochemically induced electron transfer is quantified by the Rehm–Weller equation.⁶⁹ The redox chemistry of organic molecules is considerably enriched by the photochemical electron transfer. Numerous synthetic applications have been reported.^{70,71}

In compound **44**, an intramolecular photochemically induced electron transfer takes place from an indol to a dihydroindol moiety (Scheme 5.12).⁷² After deacylation, the radical anion **XI** is generated. The presence of a lithium salt increases the polarity of the reaction medium, which stabilizes the radical ion pair with respect to back electron transfer. The lithium ion particularly stabilizes the radical anion **XI**. The presence of an OAc on the donor indole fragment facilitates the electron transfer, and yields are increased when compared to transformations of derivatives without this substituent.⁷³ Debromination at the dihydroindole moiety and radical combination lead to the intermediate **XII**. After tautomerization, the final product **45** is isolated in good yields. **45** was transformed in seven additional steps into (–)-diazonamide A.

Many photochemical electron transfer–induced reactions have been carried out with phthalimide derivatives.^{71,74} A phenomenon of chiral memory⁷⁵ has been observed in such reactions of a phthalimide derivative. The L-proline compound **46** was transformed into the benzodiazepine derivative **47** (Scheme 5.13).⁷⁶ Eighty-six percent of the chiral information was preserved in the final product **47**. In this case, the electron

SCHEME 5.12 Intramolecular photochemical electron transfer-induced macrocyclization.

SCHEME 5.13 Chiral memory effect in a photosensitized cyclization.

transfer occurs between a carboxylate function and the phthalimide moiety, which is directly excited to its triplet state (T_1) via acetone sensitization (energy transfer). Thus intermediate **XIII** is generated. For classification of this reaction, it should be added that the electron transfer itself is not sensitized. No electron transfer occurs from or to the sensitizer (acetone). The configuration of the pyrrolidine moiety in **47** has been inverted with respect to the substrate **46**. This result was explained by an enhanced barrier of the rotation around the central C–N bond of an atropisomer of intermediate **XIV** before cyclization. The biradical **XIV** also possesses triplet character. The photochemical electron transfer-induced reactions of phthalimides have been widely applied to the synthesis of macrocyclic compounds⁷⁷.

Recently, a lot of photochemically catalyzed reactions using electron transfer have been applied to organic synthesis.⁷⁸ In this case, the sensitizer is involved in photochemical electron transfer and acts as redox catalyst.⁷⁹

Electron-rich alkenes such as the silyl enol ether in compound **48** are oxidized by the photochemical excited sensitizer DCA (Scheme 5.14).⁸⁰ A cascade reaction is induced by the addition of the resulting radical cation in **XV** to an alkene. Thus the rings B and C of a steroid system are constructed. The final products **49a,b** are obtained in moderate yields. Only two stereo isomers have been obtained since the relative configuration of the created chiral centers at the junctions of rings A,B and B,C is identical in

SCHEME 5.14 Cascade reaction induced by photochemical electron transfer.

both isomers. The first cyclization leading to the formation of ring C in **XVIa,b** is unselective while the second cyclization leading to the formation of ring B is stereospecific. The same reaction was applied to the asymmetric synthesis of a triterpene derivative of damarane type.⁸¹

Despite its interest for organic synthesis, in particular for a convenient synthesis of nitrogen-containing heterocycles, the radical addition of simple tertiary amines to olefinic double bonds could not be easily carried out. Numerous side reactions such as polymerization were frequently observed. The process has therefore been applied to photochemically induced radical polymerization.⁸² However, several transformations with silylated amines have been successfully carried out.⁸³ α -Aminoalkyl radicals⁸⁴ can be produced by photochemical electron transfer. In such a case, an electron acceptor, for example, an aromatic ketone **50**, is photochemically excited (Scheme 5.15). Electron transfer from the tertiary amine (**51**) to the ketone takes place, leading to a radical ion pair **XVII** and **XVIII**. After proton transfer, neutral radicals **XIX** and **XX** are generated. α -Aminoalkyl radicals **XX** obtained in this way form pyrrolidine **51** have been added in high yields to the electron-deficient double bond of α,β -unsaturated lactones such as **52**.^{85,86} The radical addition occurred stereospecifically *anti* with respect to the alkoxy substituent but the configuration of a second chiral center in the α -position of the nitrogen atom was not controlled and two diastereoisomers **53a,b** have been isolated in high yields. The efficiency of the transformation was achieved because electron donor-substituted aromatic ketones such as **54** were used as sensitizer. The corresponding ketyl radicals (**XIX**) are particularly stable and can regenerate the sensitizer during a radical chain reaction, which considerably diminishes side reactions. Furthermore, the sensitizer is used in catalytic amounts and remains stable during the transformation. The adducts **53a** and **53b** have been transformed into the pyrrolizidine alkaloids (–)-isoretronecanol and (+)-laburnine, respectively. Under similar reaction conditions, radical tandem reactions have been carried out with unsaturated tertiary amines.^{86,87} Using inorganic semiconductors such as TiO_2 or ZnS as photochemical electron transfer sensitizers, the same transformations have been performed with heterogeneous photocatalysis.⁸⁸ An intramolecular version was performed in a template structure (compare Scheme 5.2).⁸⁹

SCHEME 5.15 Photochemical electron transfer-induced addition of tertiary amines to alkenes.

Alcohols, cyclic ethers, or acetals are added in a similar way to alkenes although the corresponding α -hydroxy or α -alkoxy radicals are not generated via electron transfer.^{78,90} In these cases, benzophenone is frequently used as sensitizer and the radicals are generated via hydrogen abstraction by the electronically excited sensitizer. The proton and the electron of the hydrogen atom are transferred almost simultaneously. With such a reaction, 1,3-dioxolane **56** was added stereoselectively to the α,β -unsaturated lactone **55** (Scheme 5.16).⁹¹ The adduct **57** was transformed into the bistetrahydrofuran **58**. Further transformations led to UIC-94017 (now also named TMC-114), which is an efficient HIV protease inhibitor. In particular, the bis-tetrahydrofuran core structure contributes as a P2 ligand.

Recently, ruthenium complexes have been used for photochemical electron transfer catalysis in [2 + 2] photocycloadditions between two α,β -unsaturated carbonyl moieties⁹² and dehalogenations.⁹³ This reaction step has been combined with organocatalysis in an efficient asymmetric alkylation of aldehydes.⁹⁴ Using an iridium catalyst (**59**⁺), an asymmetric α -fluoromethylation of various aldehydes has been performed (Scheme 5.17).⁹⁵ By addition of the organocatalyst **61**, the aldehyde **60** is transformed into the

SCHEME 5.16 Addition of 1,3-dioxolane **56** induced by photochemical hydrogen abstraction.

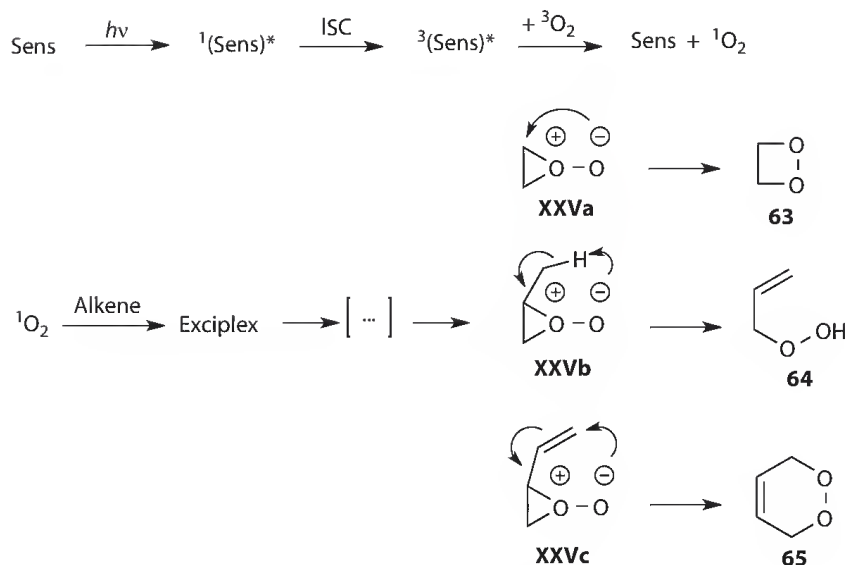

SCHEME 5.17 Photochemical electron transfer catalysis combined to organo-catalysis.

enamine **XXI**. The α -aminoalkyl radical **XXIII** is then obtained by addition the trifluoromethyl radical **XXII**. The first one is oxidized by the photochemical excited iridium complex (**59⁺**)*, leading to the iminium ion **XXIV**. Sponification leads to the trifluoromethylated aldehyde **62** in high yield and enantioselectivity. The organocatalyst **61** is regenerated, which closes the organocatalytic cycle. The neutral Ir complex **59** is a powerful reductant and by electron transfer to trifluoromethyl iodide **63**, the corresponding radical **XXII** for the addition to the enamine **XXI** is produced. The positively charged iridium complex is regenerated and the photoredox catalytic cycle is thus closed. Only 0.5 mol% of the photocatalyst **59⁺** was added while 20 mol% of the organocatalyst **61** was needed. The reaction has also been performed with various aldehydes and higher fluoralkyl iodides as well as with fluoralkyl iodides carrying functional groups.

5.5 Photo-Oxygenation

Molecular oxygen belongs to the small family of compounds possessing triplet multiplicity at the ground state. The reactivity, in particular with organic molecules at the singlet ground state, is therefore reduced. Singlet oxygen in contrast is very reactive also due to the high electronegativity of oxygen. Nevertheless, photo-oxygenations are often highly selective. Most frequently, the photo-oxygenation of alkenes have been applied to organic synthesis (Scheme 5.18).⁹⁶ Singlet oxygen is most conveniently produced via photochemical sensitization. Due to the low excitation energy of the S_1 state (22.5 kcal mol⁻¹), dyes are used as sensitizers, and the excitation can also be carried out with visible light. After light

SCHEME 5.18 Generation of singlet oxygen and reaction with alkenes.

absorption of the sensitizer, intersystem crossing (ISC) occurs. Possessing triplet multiplicity (T_1), the sensitizer can now easily interact with oxygen in the triplet ground state (T_0). The oxygen is thus excited at the S_1 state and the dye sensitizer returns to its singlet ground state (S_0).

The first intermediate in the reaction of singlet oxygen with alkenes is an exciplex. Various other intermediates are described in the literature. The most significant ones used to explain the formation of the final products are **XXVa,b,c**. Depending on the structure of the alkene, three main types of products are obtained: dioxetanes **63**, hydroperoxides **64** from an ene reaction, and endoperoxides **65** from a pseudo Diels–Alder reaction. Aside these reactions, singlet oxygen also induces electron transfer leading to $\text{O}_2^{\cdot-}$.⁹⁷

Recently, the ene reaction was applied to the synthesis of 1,2,4-trioxanes. This functional group is a partial structure of artemisinin and structural analogues (Scheme 5.19). These compounds originate from traditional Chinese medicine and possess antimalarial activity, which is essentially linked to the 1,2,4-trioxane moiety.⁹⁸ This structure can be easily built up using photo-oxygenation of allyl alcohols followed by acetalization with a ketone. For example, allyl alcohol **66** was transformed into hydroxyhydroperoxide **67a,b**, which was obtained as a mixture of diastereoisomers.⁹⁹ Acetalization with adamantone **68** yielded the final product **69**, which possesses high in vitro antimalarial activity.¹⁰⁰ A large variety of 1,2,4-trioxane can easily be synthesized in this way.¹⁰¹ Homoallyl alcohols were photo-oxygenated in the same way. Thus, 1,2,4-trioxepanes such as compound **70** are available.¹⁰² This product possesses interesting in vivo antimalarial activity, which is certainly also favored by the presence of the polar amino group. A 1,2,4-trioxane was also attached to artemisinin as in **71**.¹⁰³ Such compounds may also possess cytostatic activity. Dihydroxyhydroperoxides have been transformed into 1,2,4-trioxane possessing an additional orthoester group.¹⁰⁴ These fragments were also attached to artemisinin.

Many pseudo-Diels–Alder reactions of singlet oxygen with furans have been applied to organic synthesis. Thus, addition of singlet oxygen to furfural **72** leads to the corresponding adduct **XXVI** (Scheme 5.20). The formation of this adduct occurs via an intermediate of type **XXVc** (Scheme 5.18). Addition of methanol used as solvent leads to hydroxyfuranone **73** in high yields.¹⁰⁵ When the reaction is carried out at $T > 40^\circ\text{C}$, acetalization is completed and methyloxyfuranone is obtained.¹⁰⁶ The reaction was also efficiently carried out with visible light, in particular sunlight.¹⁰⁷ The acetalization can also be carried out with chiral alcohols such as (–)-menthol **74**.^{87,108} Two diastereoisomers of menthyloxyfuranone **75a,b** are thus obtained in a 1:1 ratio. The isomer **75a** possessing 5*R* configuration crystallized preferentially and the isomer **75b** can partially be transformed into **75a**. When the acetalization of **73** is carried out with (+)-menthol **ent-74**,^{109,110} the menthyloxyfuranone **ent-75a** possessing 5*S* configuration is obtained. Both isomers of the chiral synthon

SCHEME 5.19 Synthesis of 1,2,4-trioxanes using photo-oxygenation of alkenes.

SCHEME 5.20 Synthesis of menthyloxyfuranone.

are thus available, which permits a versatile application to asymmetric synthesis. The reason is that almost all reactions are highly or completely diastereoselective and the configuration of the chiral center generated in the β -position of the α,β -unsaturated lactone can be predicted.⁸⁷ The chiral synthons **75** or **ent-75** were widely applied to asymmetric synthesis. Natural products, nitrogen-containing heterocycles, various amino acid derivatives, aromatic and pheromone derivatives, chiral ligands for asymmetric catalysis, and products possessing a biological activity of pharmaceutical or agrochemical interest have been synthesized.^{110,111}

The 5-hydroxyfuranone moiety is a partial structure of numerous natural terpene compounds belonging to various product families such as labdanes¹¹² or eremophilanoides.¹¹³ Generally, this partial structure is built up by photooxygenation of a furane moiety. A lot of such syntheses are reported in the literature. For example, the furan derivative **76** was successfully photooxidized to hydroxyfuranone **77** (Scheme 5.21, Equation 5.10).¹¹⁴ The reaction is regioselective. After, saponification, the labdane compound sibiricinone

SCHEME 5.21 Selective photo-oxygenation of furan moieties.

A was obtained. Frequently, these reactions are performed in methylene chloride at low temperature with rose bengal as sensitizer and the isolated yields are generally higher than 90%.¹¹⁵ In the same way, the silylated furan **78** was transformed into hydroxyfuranone **79** (Equation 5.11).¹¹⁶ The presence of the tributylsilyl group (TBS) at the furan ring increases the efficiency so that **79** was isolated in quantitative yield. Furthermore in many transformations, this substituent determines the regioselectivity.¹¹⁷ After deprotection in **79**, the eremophilane compound (±)-toluccanolide C was obtained.

The hydroxyfuranone moiety is in equilibrium with the γ -keto- α,β -unsaturated butyric acid form. Under particular reaction conditions, the second form can be targeted. This transformation was applied to complex total syntheses. The silylated furan derivative **80** was photooxygenated (Scheme 5.22).¹¹⁸ Intermediately, the hydroxyfuranone **XXVII** was formed. In a second transformation, this compound was transformed into the unsaturated ketoester **81**. The overall yield of these two reactions was almost quantitative. The α,β -unsaturated ketone in **81** was then transformed into a dienolsilylether (**82**). A Diels–Alder reaction was carried out under thermolysis conditions leading to the tricyclic compound **83** as a mixture of regioisomers. Desilylation of the latter compound yielded the tricyclic diketone **84**, which was transformed into the alkaloids, zoanthamine and norzoanthamine. Such compounds possess several interesting pharmaceutical activities. For example, norzoanthamine derivatives strongly inhibit the growth of murine leukemia cells and possess antiplatelet activities. Compound **84** constitutes the tricyclic partial structure of rings A, B, and C of the target compounds with the correct relative configuration. Numerous other transformations the hydroxyfuranone fragment can be envisaged as key steps in total syntheses. Thus, the carbonyl function of the open structure was transformed in a Wittig reaction. This strategy was successfully applied to the synthesis of milbemycin G and (6*R*)-6-hydroxy-3,4-dihydromilbemycin E.¹¹⁹

5.6 Photochemically Supported Organometallic Reactions

Although carried out under thermic conditions, organometallic reactions are frequently accelerated under photochemical conditions.¹²⁰ Heating and concomitant irradiation become standard reaction conditions as in the case of the Vollhardt reaction.¹²¹ This [2 + 2 + 2] photocycloaddition of three acetylene functions leads to aromatic compounds and is carried out with cheap cobalt catalysts. The reaction was also used for the synthesis of pyridines from two alkyne and one nitrile moiety.¹²² In this case, detailed investigations on the influence of light irradiation on the efficiency was carried out¹²³ and the reaction was, for example, applied to the synthesis of axial chiral biaryl compounds containing a naphthalene and a pyridine moiety.¹²⁴ Asymmetric catalysis was used to induce chirality.

SCHEME 5.22 Photo-oxygenation of a furan moiety and transformation into a γ -keto- α,β -unsaturated butyric acid derivative.

A similar reaction is observed between two alkyne and one alkene moiety. In this manner, cyclohexadienes are obtained. This reaction was used to build up the tricyclic system of pasteurestin B by the transformation of unsaturated compound **85** into **86** (Scheme 5.23).¹²⁵ Cobalt remains attached to the cyclohexadiene partial structure. Treatment with Cu^{2+} at the end of the reaction leads to demetallation. With the same strategy, pasteurestin A was synthesized. These compounds are potential antibiotics for veterinary applications. This method as well as the cyclotrimerization of alkynes

SCHEME 5.23 Intramolecular cobalt-catalyzed [2 + 2 + 2] cycloaddition.

SCHEME 5.24 Photochemical transformation of Fischer-type carbene complexes.

provides a general approach to polycyclic systems, for example, steroid- or taxane-like structures.¹²⁶ Complex benzocyclobutenes structures are also easily available.¹²⁷

Numerous photochemical transformations of Fischer-type carbene complexes have been applied to organic synthesis.^{128,129} Upon irradiation, chromium carbon complexes of type **87** are transformed into ketenes, which are linked to the chromium atom **XXVIII** (Scheme 5.24, Equation 5.12).¹²⁹ A cyclopropane **XXIX** structure is also discussed. These intermediates readily react, for instance, with nucleophiles, undergo [2 + 2] cycloaddition with different unsaturated compounds such as alkenes or imines or they undergo electrocyclizations. The latter reaction was carried out with the indol derivative **88** (Equation 5.13).¹³⁰ Upon irradiation under carbon monoxide, compound **88** yields first the ketene intermediate **XXX**. Electrocyclization and loss of the chromium carbonyl complex leads to the final product **89**.¹³¹ The catechol derivative **89** was transformed into the alkaloid carbazoquinocin-C possessing an *ortho*-quinone moiety. This compound family possesses activity against lipid oxidation and neuronal protecting properties.

Similar reactions were successfully carried out with tungstenhexacarbonyl.¹³² In most of these cases, no intermediate metal complex is isolated. Thus the reaction was applied to the synthesis of substructures of altromycin B, a pluramycin antibiotic.¹³³

Metal-catalyzed oxidations are also improved by light irradiation. Thus the oxidation of primary alcohols to aldehydes using TEMPO and Cu⁺ as catalytic system and air as oxidant was accelerated by irradiation with visible light.¹³⁴ The reaction was selectively carried out with hexoses derivatives and applied to the efficient synthesis of tetrahydroxyazepanes. These compounds are interesting due to numerous pharmaceutical activities such as the inhibition of glycosidases or glycosyltransferases. Similar effects of light irradiation on the aerobic oxidation kinetics have been observed with ruthenium catalysts.¹³⁵ Osmium tetroxide catalyzed *cis*-hydroxylation is easily carried out with a large variety of alkenes.¹³⁶ Due to the aromatic stability in benzene-type aromatics, these compounds cannot be hydroxylated under standard reaction conditions. However, when the reaction mixture is irradiated, aromatic compounds such as benzene or toluene are stereoselectively oxidized.¹³⁷ Although the yields remained low, this reaction considerably simplified the synthesis of inositol derivatives such as (±)-pinitol. Optimizing this transformation would significantly enrich the synthetic chemistry associated to *cis*-dihydrodiol.¹³⁸

Studies of mechanistic details of the organometallic reactions such as the Suzuki or the Sonogashira reaction led to the conclusion that some partial steps may be photochemically carried out thus avoiding the use of metal catalysts.¹³⁹ Such transformations have been carried out; they are based on a photo-S_N1 reaction of aromatic compounds involving phenyl cation intermediates.

5.7 Further Reactions

Photochemical excitation is involved in numerous other transformations of interest in organic synthesis. Many radical reactions are photochemically induced. In most cases, the photochemical step is not particularly studied since the radical intermediates are also generated by thermal reaction.¹⁴⁰ The interest is mostly focused on the radical reaction steps. Recently, photochemical reaction conditions have been applied to the transformation of thiocarbonyl compounds. This functional group is able to add reversibly to radical intermediates and thus control the overall reaction. In this function, they have been applied to organic synthesis¹⁴¹ and to radical polymerization (RAFT).¹⁴² In the present example, the dithiocarbamate **90** was irradiated with visible light leading to fragmentation of a C–S bond (XXXI) (Scheme 5.25).¹⁴³ Intramolecular addition of the acyl radical and trapping with the dithiocarbamyl radical leads to the bicyclic lactame **91**. In a second photochemical step using UV light and in view of an oxidation, the dithiocarbamate function in **91** was exchanged by TEMPO (**92**). Treatment with *meta*-chloroperbenzoic acid led to keto lactame **93**. Further transformations led to the tricyclic compound **94**, which can be transformed into (–)-aphanorphone as previously described. The method was applied to the synthesis of numerous nitrogen-containing cyclic and isocyclic compounds.¹⁴⁴ The presence of thiocarbamates in the reaction mixture also accelerates photochemical-induced radical addition of amines to alkenes.¹⁴⁵

In the multistep synthesis of complex polyfunctional compounds, protecting groups are often necessary and must be meticulously chosen. On one hand, they must resist the transformation conditions of other functional groups and on the other, they must be removed without damaging the core structure. In most cases, acidic or basic reagents are used for deprotection. Metal and enzymatic catalysis have also been used. The major advantage of photochemical protecting groups is that no chemical reagents are needed for deprotection and removal is rapid and clean in most cases.¹⁴⁶ These properties are particularly suitable for applications in the fields of biochemistry and microbiology and other application domains can easily be prospected.¹⁴⁷ In a recent example of a total synthesis, an *ortho*-nitrobenzyl protecting

SCHEME 5.25 Photochemically induced radical reaction.

SCHEME 5.26 Photochemical removal of a protecting group.

group is efficiently eliminated from the substrate **95** in the last step of the synthesis of *ent*-fumiquinazoline (Scheme 5.26).¹⁴⁸ After photochemical excitation, hydrogen transfer occurs from the benzyl position to the nitro function yielding intermediate **XXXII**. This species is in equilibrium with the bicyclic intermediate **XXXIII**. *ortho*-Nitrobenzaldehyde **96** is now eliminated from these intermediates. Recently, ruthenium complexes have been used for photochemical electron transfer catalysis and deprotection with photolabile protecting groups have been carried out in this manner (compare Section 5.4).¹⁴⁹

Despite the advantages that photochemical reactions present when used as key steps in numerous organic syntheses, organic chemists sometimes hesitate to make use of them. Sometimes it is assumed that photochemical reactions are difficult to reproduce or to scale up. However, as any other chemical transformation, these reactions are well reproducible and can easily be scaled up when the reaction parameters are well chosen and optimized. For example, changing the scale often needs an adaptation of concentrations and geometry of the reaction vessel in order to fulfill the conditions of optimal absorption according to the Lambert–Beer law. The very broad scale of photochemical transformations applied to organic synthesis is best illustrated by industrial processes¹⁵⁰ such as the preparation of rose oxide using photo-oxygenation of citronellol as a key step^{107,150,151} or the synthesis of vitamin D using a photochemical electrocyclic rearrangement of 7-dehydrocholesterol (provitamin D)¹⁵² as a key step. On the other hand, a large variety of photochemical reactions are very successfully performed in microreactors.¹⁵³ Very delicate transformations in which, for example, both the substrate and the product are photoreactive have been can also be carried out with particularly adapted and easily constructed equipment.^{40,42}

Photochemical transformations are frequently discussed in the context of green chemistry since often chemical activation is avoided and thus waste can be diminished.^{154,155} In this context, photochemical reactions are particularly attractive when they can be carried out with sunlight as renewable energy source.^{107,151,154,156}

5.8 Conclusions

Photochemical reaction steps are applied in almost all fields of organic synthesis. The present chapter mainly focuses on total syntheses of natural products and compounds possessing biological activity. Photochemical excitation changes completely the properties of a chemical compound. Under these conditions, transformations can be carried out, which are not possible at the ground state. Thus starting from easily available

products, complex and highly target related structures are built up in only one step. In many cases of complex syntheses, the number of steps is considerably reduced. Often no chemical activation (acids, bases, metal catalysts, ...) is needed and optimized irradiation apparatus also facilitates an industrial application. In some fields of organic synthesis such as radical reactions, photochemical conditions are well established. In other fields such as organometallic reactions, it is less the case. However, many of these reactions are performed under drastic conditions or with expensive catalysts, which also limit the tolerance of functional groups. Under photochemical conditions, often the reactions are accelerated, yields and selectivity are increased, and the transformations can be performed with simple and cheap catalytic systems. A more systematic study of these reactions and their application to synthesis is therefore highly recommended.

6.1 Introduction

The term “photochirogenesis” was coined by one of the present authors in 1996 when the ERATO Photochirogenesis Project¹ was launched and is conceptually synonymous to more traditional “asymmetric photochemistry” or “chiral photochemistry” with some emphasis on the creation of molecular chirality by photon. A photochirogenic reaction may involve the enantioselective destruction of a racemic mixture or the enantio- or diastereodifferentiating creation of a new stereogenic center in prochiral or chiral substrate through the electronically excited state.

Synthesis of chiral compounds that are difficult to obtain by thermochemical reactions but readily accessible by photochemical reactions is certainly one of the major motivations for promoting the study on photochirogenesis. The photochemical routes to chiral compounds are particularly efficient or even essential for the construction of such compounds that are thermally unstable, highly constrained, and/or polycyclic. The switching of chemo- and stereoselectivity, often observed upon photoexcitation as a consequence of the promotion of an electron to the antibonding orbital and the subsequent alterations in reactivity and redox properties, renders the photochirogenic route an attractive alternative to the conventional catalytic and enzymatic counterparts. Indeed, the photochirogenesis has now become an indispensable and practical protocol for synthesizing molecules of complex structures, such as naturally occurring and bioactive complex organic compounds.²

The very wide range of temperature available for most photochemical processes is obviously another crucial advantage for photochirogenesis over the conventional catalytic and enzymatic asymmetric syntheses that work only in much narrower temperature regions. Executing photoreactions at a lower temperature not only enhances the chemo- and stereoselectivities in general but also makes easier the detection and trapping of reaction intermediates as well as the elucidation of reaction mechanisms.

The use of pulsed laser irradiation enables us to directly observe the transient species and reaction intermediates of very short lifetimes and obtain the information about rapidly occurring excited-state events.³ It is also to be noted that photochirogenesis has an inherent advantage for mechanism elucidation over usual achiral photoreactions, as the stereochemical outcomes contain rich information about the conformational and/or configurational changes experienced in a photochirogenic process.

As a result of the intensive studies particularly in the last two decades, this highly interdisciplinary area of photochemistry and asymmetric synthesis has seen a considerable growth in the numbers of researchers and publications and also the expansion of its scope and limitations. Nevertheless, it is also true that the studies so far do not cover the whole of the photochirogenic reactions, the optical yields reported hitherto are not fully satisfactory, and the factors and mechanism controlling the stereodifferentiation process in the excited state are not completely elucidated.

In this chapter, we will only briefly mention about the historical background and the earlier studies but rather focus on the most recent developments in photochirogenesis research published in the last 10 years, which are classified in terms of the source of chirality and the reaction media employed. For the earlier work in photochirogenesis, readers are directed to the excellent reviews published previously.⁴⁻⁷

6.2 Photochirogenesis with Circularly Polarized Light

The use of circularly polarized light (CPL) in chiral photochemistry is based on the fact that an enantiomeric compound exhibits the circular dichroism or ellipticity, possessing distinctly different molar extinction coefficients for left- and right-handed CPL (ϵ_l and ϵ_r), and therefore, one of the enantiomeric pairs can be preferentially phototransformed upon CPL irradiation at an appropriate wavelength where the circular dichroism intensity ($\Delta\epsilon = \epsilon_l - \epsilon_r$) is not zero. This process may be called as photochemical kinetic resolution or deracemization. Since the enantiomeric enrichment is achieved by physical chiral source (i.e., CPL) without using any chiral reagent, auxiliary, or catalyst, CPL-induced chirogenic photoreaction is sometimes referred as “absolute” asymmetric synthesis. However, this may be misleading as CPL does not create any stereogenic center but simply induce an enantiomeric imbalance in the chiral, but racemic, substrate used as a starting material.

The possible use of CPL for inducing molecular chirality was proposed by van't Hoff⁴ and le Bel⁸ as early as mid-nineteenth century, but it took half a century until the Kuhn's first experimental proof of CPL photochirogenesis using a racemic mixture of α -azidopropionamide and bromopropionate.⁹ The mechanistic studies on a variety of CPL-induced photochirogenic reactions flourished in 1970s. However, the use of CPL has never been considered as a practical tool for preparative asymmetric synthesis, simply because the generally low anisotropy factors ($g = \Delta\epsilon/\epsilon$) reported so far hinder the efficient photochemical enantiomeric enrichment by CPL.

Intriguingly, CPL photochemistry may be related to the origin of the terrestrial homochirality, or the extreme enantiomer imbalance. The origin of homochirality in biosphere is still a target of intensive researches and debates, and hence attracts much attention of scientists.¹⁰⁻¹³ Of several hypothetical theories and potential mechanisms that have been proposed to explain the terrestrial homochirality, the one proposed originally by Bonner and Rubenstein in mid-1980s¹⁴ and further developed by others^{13,15} is directly related to the CPL photochemistry, claiming that the enantioselective photodecomposition of racemic organic compounds such as amino acid was induced by the CPL from a neutron star or a star formation region to leave the enantiomerically enriched compounds, which were ultimately delivered to the primitive earth. This theory was supported by the facts that (1) a variety of natural and non-natural amino acids were found in the organic mantle of the Murchison meteorite, some of which were enantiomerically enriched, (2) the extraterrestrial origin of these amino acids was confirmed by the deviation of the $^{13}\text{C}/^{12}\text{C}$ and $^{15}\text{N}/^{14}\text{N}$ ratios from those found on earth, and (3) the off-plane radiation from an electron storage ring is elliptically polarized and indeed the circularly polarized infrared radiation was observed from the reflection nebulae in the star formation regions.^{13,16}

In this relation, it is crucial that a variety of nonaromatic amino acids were found in a photolyzate from the vacuum-UV irradiation of a 2:1:1:1 mixture of water, methanol, ammonia, carbon monoxide, and carbon dioxide at 12 K, despite the low combined quantum yield ($\Phi \sim 10^{-4}$).^{13,16} Furthermore, in the CPL photolysis of racemic leucine in 0.1 M aqueous HCl solution, it was shown that the use of l-CPL at 212.8 nm, which is preferentially absorbed by (S)-leucine, enriches (R)-leucine to give an enantiomeric excess (ee) of 2.5% at 75% conversion.¹⁷ These results support the Bonner–Rubenstein theory that the CPL photolysis of racemic amino acids in the outer space is a source of chirality imbalance in biomolecules occurring on the earth.

More recently, the chiroptical property, CPL photolysis, and photodecomposition mechanism of several aliphatic amino acids were comparatively studied in aqueous solutions at different pH values.^{18–21} These studies revealed that (1) the chiroptical properties, particularly anisotropy (g) factor, of amino acid are highly sensitive to solution pH, with the g factor maximizing at pH 1, (2) glycine and alanine photodecompose only slowly to give ammonia and the corresponding α -hydroxycarboxylic acid, and (3) in sharp contrast, higher amino acids with γ -hydrogen, such as valine, leucine, and isoleucine, efficiently photodecompose to give glycine as a major, common product at acidic pH values via the Norrish type II mechanism, but more slowly to α -hydroxycarboxylic acid through an α -lactone intermediate at neutral pH. The ee values obtained upon photolysis with synchrotron-generated CPL at 215 nm are also pH-dependent, and L-leucine of 1.3% ee was obtained after 55% of the racemic leucine used was decomposed by l-CPL irradiation.

Then, amplification or self-replication of the enriched enantiomer becomes critical for further validating the Bonner and Rubenstein's theory. At present, no chirality amplification is known for photochemical reaction, but autocatalytic reactions have been reported by Soai et al.²² They demonstrated that the small initial imbalance of molecular chirality generated by CPL can be significantly amplified.^{23,24} Thus, racemic pyrimidyl alcohol **1** was subjected to photolysis with r- or l-CPL to give slightly (R)- or (S)-enriched **1**,²³ which was added to a solution containing 2-alkynylpyrimidine carbaldehyde **2** and diisopropylzinc without purification as a “seed of chirality” for self-catalytic synthesis of **1**. Excellent ee's >99.5% were achieved after three rounds of consecutive asymmetric autocatalysis.

On the other hand, the different physical properties of conglomerate *versus* racemate could be another possible cause of chiral amplification. For example, Breslow et al. demonstrated that conglomerate crystals of some L-amino acids show much higher solubilities in aqueous solution than more stable racemate crystals, allowing chiral discrimination upon crystallization/dissolution process.²⁵ Soloshonok et al. reported the enantiomeric self-purification of nonracemic α -trifluoromethyl lactic acid through sublimation²⁶ and of β -amino acid derivatives through disproportionation in the achiral phase of chromatography.²⁷

An interesting application of CPL has recently been reported for the preparation of chiral polydiacetylene films by Iwamoto et al.^{28–31} CPL irradiation of monomer films of 10,12-tricosadiynoic acid derivatives **3** and **4** deposited on a fused silica substrate gave polydiacetylene films **5** and **6**, respectively. The polydiacetylene films obtained by irradiating *r*- and *l*-CPL showed the apparent CD signals at 500–700 nm of opposite sign, which was ascribed to the helical structure of the opposite chiral sense. The strong CD signals remained even after the polymer suffered a thermochromic change upon heating at 80°C for 10 min. Although a chiral LB film of polydiacetylene has been obtained previously under specific conditions from achiral monomers, its formation was rather unintended and the sign of chirality was uncontrollable.³²

6.3 Photochirogenesis in Fluid Solution

Of various reaction media ever examined for photochirogenesis, fluid solutions have been most frequently and extensively employed, enabling less substrate- or conformation-dependent, more comprehensive, and chiral-source efficient photochemical transformations as well as the dynamic and external control of chemo- and stereoselectivities, when compared with the solid state. An important progress has been made in solution-phase photochirogenesis by using the unconventional media, such as supercritical fluid and ionic liquid, which possess novel intriguing properties distinctly different from those of conventional solvents.

6.3.1 Photochirogenesis in Organic Solution

6.3.1.1 Intramolecular Photochirogenesis in Organic Solution

Diastereodifferentiating photoreaction necessitates a stoichiometric amount of chiral auxiliary attached to the photoreactive prochiral moiety of substrate, but generally affords one of the two possible diastereomeric photoproducts in good-excellent selectivity, particularly for [2 + 2], [4 + 2], and [4 + 4] photocycloaddition.³³ This is simply because the intramolecular steric and electronic interactions of the chiral auxiliary with the photoreactive moiety are stronger, more effective, and long-lived in general than those attained upon intermolecular diastereodifferentiation or enantiodifferentiating photosensitization described in Sections 6.3.1.2 and 6.3.1.3.

Some of diarylethenes are typical photochromic compounds at ambient temperatures, which are highly durable for the reversible photoconversion between the “open” and “closed” forms upon irradiation at specific wavelengths.³⁴ Generation of new chiral centers in the closed-ring isomer is one of the characteristic properties of diarylethene derivatives. This feature makes the diarylethenes potentially useful for nondestructive readout in optical memories by detecting the change in optical rotation.^{35,36} Yokoyama et al. investigated the diastereodifferentiating photoinduced ring-closure reaction of chiral diarylethenes **7O**–**11O**.^{37–40} The ring-closure reactions of **7O**, **8O**, and **9O** carried out in ethyl acetate at room temperature are highly diastereodifferentiating, affording **7C**, **8C**, and **9C** in 98%, 98%, and 95% diastereomeric excess (de), respectively. The diastereoselectivity was manipulated moderately by changing the reaction temperature. Upon irradiation at –67°C, the de values were enhanced to 100% for **7C**

and 99% for **8C**, but decreased to 89% for **9C**. Photolysis of **10O** gave **10C** in a much lower 47% de, which however showed a remarkable difference (1300°) in specific rotation from the open form at the photo-stationary state. Photoirradiation of **11O** with UV light in ethyl acetate led to highly diastereoselective photocyclization (90% de) and a large change (950°) in specific rotation at 633 nm.

West et al. have recently reported the diastereodifferentiating intramolecular [4 + 4] photocycloaddition of 4-mesyloxypyran-2-one derivatives.⁴¹ Photocycloaddition of **12** gave **13** and **14** in a diastereomeric ratio (dr) of 1.4:1 (58% de) in 69% combined yield in aqueous methanol at 0°C. In toluene at -78°C, the dr was improved to 4.2:1 (81% de) with keeping the chemical yield at 64%.

One of the intriguing topics in photochirogenesis study is the memory of chirality.^{42–44} Griesbeck et al. reported the stereoselective synthesis of pyrrolo[1,4]benzodiazepines **16a–d** through decarboxylative photocyclization of **15a–d**.⁴⁵ The reaction involves a photoinduced intramolecular electron transfer process from the carboxylate anion to the electronically excited phthalimide, followed by CO_2 extrusion and subsequent recombination of the resulting radical pair. Photolysis of proline derivatives **15a,b** led to the exclusive formation of *trans*-photoproducts **16a,b**. Despite the intermediacy of a triplet 1,7-diradical, the photocyclization proceeded highly enantioselectively to give **16a** in 86% ee. Moreover, photodecarboxylation of **15c,d** proceeded with a complete inversion of the configuration at the stereogenic center to give **16c,d** as sole products. The high degree of chirality memory was interpreted in terms of the high activation barriers for the rotation about the central C–N bond, which helped preserving the absolute axial chirality during the course of the reaction.

Garcia-Garibay et al. reported the memory of chirality upon recombination of a radical pair produced in the photolysis of chiral bis(phenylpyrrolidinonyl)ketone **17** in solution.^{46,47} Ketone **17** was photodecomposed in a low quantum yield of 0.05, suggesting that the geminate recombination of ketyl radical is much faster than decarbonylation. On the other hand, the rate of decarbonylation k_{CO} should be faster than the rotation rate of radicals formed in the first step, as no epimerization was observed for ketone. Photolysis of enantiopure (*S,S*)-**17** gave stereo-retained (*S,S*)-**18**, single inverted (*R,S*)-**18**, and double inverted (*R,R*)-**18** in 70%, 21%, and 9% yield, respectively. The solvent-caged effect appears to be responsible for the efficient chirality memory. At a higher temperature, the yield of (*S,S*)-**18** decreased to 50%, while those of (*R,S*)- and (*R,R*)-**18** increased to 35% and 15%, respectively. These results are satisfactorily rationalized in terms of the accelerated rotation of radicals at the higher temperature; the rotation time constants ($1/k_{\text{rot}}$) for the radicals generated by the photolysis were estimated to be 6.5 ps at 25°C and 3.2 ps at 69°C.

Sakamoto et al. investigated the chiral memory effect observed in the β - and γ -hydrogen abstraction reactions of thioimides.^{48,49} Photochemical reactions of thioketones are known to proceed through S_2 ($\pi\pi^*$) and T_1 ($n\pi^*$) state. Similar to thioketone, excited thioimides are prone to abstract intramolecular hydrogens. Upon photoexcitation, **19** abstracts a β -hydrogen to give a 1,3-biradical intermediate, which in turn rearranges to give **20** with accompanying conversion of the chiral tertiary carbon to a chiral quaternary carbon. Thus, the irradiation of enantiopure **19a–d** with a high-pressure mercury lamp leads to the formation of the corresponding thioketones **20a–d** in quantitative yields and 97%–100% ee. The extremely high level of chirality memory suggests that the photoreaction proceeds through a singlet excited state and the resulting singlet 1,3-biradical is short-lived and hence rapidly rearranges to **20** without accompanying racemization at the original stereogenic center. No hydrogen abstraction reaction was observed for monothioimide **19e**, presumably due to the lack of stabilizing phenyl group as well as the presence of destabilizing ester group. The chiral memory effect has also been examined with optically pure thioimide **21**, which undergoes the γ -hydrogen abstraction reaction to give **22** and **23**. Photoirradiation of (*S*)-**21** yielded a mixture of (3*R*,4*S*)-**22** (>50% yield) and a small amount of (3*R*,4*R*)-**22** (10%–13% yield) and **23** (15%–23% yield). Both (3*R*,4*S*)-**22** and (3*R*,4*R*)-**22** were obtained in significantly high ee's (>85%).

Sivaguru et al. have recently examined the enantiospecificity in the Norrish/Yang type II reaction of α -oxoamides **24** and the photocyclization of acrylanilides **27**.^{50–52} These compounds exhibit the non-biaryllic atrop isomerism as a consequence of the restricted rotation about the N–C(aryl) bond and are axially chiral. The isolated enantiomers of axially chiral α -oxoamides **24** can be stored at 0°C for months without racemization. Photolysis of **24** gave cyclization product **25** in >95% yield, along with a small amount of demethylation product **26**.⁵¹ Good enantiospecificity was observed for **25**, showing an efficient chirality delivery from axial to point chirality. The enantiomer ratio of **25a** was found to depend on the reaction temperature, displaying an increase from 74:26 (48% ee) at 40°C to 90:10 (80% ee) at –40°C.

The memory of chirality was also examined with the photolysis of acrylanilide **27**.⁵² The rotation about the N–C(aryl) bond in **27** is hindered by the steric bulk of the vinyl moiety. The constraint around the N–C bond leads to two atropisomers of opposite optical activity, which slowly interconvert in the ground state but not in the excited state. Upon photoirradiation, acrylanilide **27** undergoes conrotatory 6π -photocyclization to yield *cis*-**28** and *trans*-**29**. Acrylanilide **27d** bearing a β -CH₃ substituent gave **29d** in 94% ee in methanol, while **27f** with a β -H afforded racemic **29f**. Thus, the β -substituent R₁ serves as an important “messenger” or “commander” for transferring the axial chirality in reactant to the point chirality in photoproduct.

Compared to the aforementioned diastereodifferentiating photoreactions that are controlled by a chiral auxiliary covalently bonded to the substrate moiety, the photochemical enantiodifferentiation to manipulate the formation of two energetically equivalent enantiomeric products is obviously much more challenging, relying only on the weak noncovalent interactions of prochiral substrate with chiral source. Indeed, most of the enantiodifferentiating photoreactions in solution give only poor enantioselectivities.^{5,7} The supramolecular approach,^{53,54} which utilizes the noncovalent interactions in both ground and excited states, has proven a convenient, versatile methodology for controlling thermodynamically the molecular assembly and kinetically the subsequent photochirogenic reaction.

Bach et al. synthesized a series of Kemp's acid derivatives **30a–d** as chiral hydrogen-bonding templates for the use in various intra- and intermolecular enantiodifferentiating photoreactions. The enantiodifferentiating intramolecular photocycloaddition of prochiral 2-quinolone allyl ether **31** was studied in the

presence of chiral template **30a–c**. Although hydrogen-bonding templates may often self-aggregate to yield hydrogen-bonded homodimers, this is not the case with **30a,b** ($K_{\text{dim}} \sim 0 \text{ M}^{-1}$) as a consequence of the steric hindrance of the bulky tetrahydronaphthalene fence. Instead, the amide moiety of **30a,b** efficiently forms dual hydrogen bonds with **31**. One of the enantiofaces of **31** is shielded by the tetrahydronaphthalene fence, and therefore, the intramolecular attack of the allyl is allowed only from the open face. Photoirradiation of **31** in the presence of template **30b** at -60°C yielded **32** in 93% ee.^{55,56} By using **30a** as a chiral hydrogen-bonding template, similar intramolecular [2 + 2] photocycloaddition reactions of **33** and **35** in toluene at -60°C afforded **34** in 59%–75% ee and **36** in 74%–92% ee.⁵⁷ The stereochemical outcomes were significantly enhanced by increasing the amount of template, lowering the temperature, and decreasing the polarity of solvent.

In the presence of chiral template **30a**, enantiodifferentiating 6π -photocyclization of acrylanilides **37a–c** afforded photoproducts **38** and **39** in ratios ranging from 48:52 to 27:73. The ee's of **38** and **39** were enhanced up to 57% and 39%, respectively, by increasing the template/guest ratio and lowering the temperature.^{58,59} The Norrish–Yang cyclization of imidazolidinones **40** to *endo*- and *exo*-products **41** and **42** was carried out in the presence of chiral templates **30a–d**.^{56,60} The *exo/endo* ratio of the products formed from **40c** was dramatically switched from 38/62 in the absence of chiral template to 90/10 in the presence of **30c**. The photocyclization of **40** in the presence of chiral template **30a,b** afforded **41** in up to 60% ee.⁵⁶

6.3.1.2 Intermolecular Photochirogenesis in Organic Solution

Stereochemical control in photochirogenesis is tricky in general and sensitive to substrate geometry. Therefore, photochirogenesis with singlet oxygen, the smallest possible cyclophile, is considered as a great challenge. Recently, an efficient stereochemical control was achieved in $[2 + 2]$ photocycloaddition of $^1\text{O}_2$ to oxazolidinon-functionalized enecarbamates **43** possessing chiral auxiliary. Oxazolidinone-substituted chiral enecarbamates (*Z*)/(*E*)-**43** are versatile substrates for investigating the conformational, stereoelectronic, and steric effects on the stereodifferentiating singlet oxygenation of the alkene functionality.^{61–66} No enantioselectivity was observed upon cycloaddition of $^1\text{O}_2$ to unsubstituted enecarbamate **43a** and **b**. However, the singlet oxygenation of (*4R*)-**43b** and (*4R*)-**43c** afforded (*1S,2S*)-**44b** and (*1S,2S*)-**44c** in >90% ee, irrespective of the configuration at the C-3 position. The carbonyl group does not appear to play a significant role in the determination of the stereochemical course of cycloaddition, as the diastereomer ratio did not show any dependence on the solvent polarity. The π -face selectivity observed upon $^1\text{O}_2$ attack was reasonably attributed to the effective shielding by the *R*-substituent at C-4 of enecarbamate **43**. Interestingly, the photolysis of a diastereomeric mixture of (*3R,4R*)- and (*3S,4R*)-**43c** to a low conversion (<30%) and the subsequent decomposition of the resulting dioxetane gave enantiomerically enriched methyldeoxybenzoin (MDB) in ca. 33% ee. At higher conversions, the ee of MDB was reduced.⁶¹ These results indicate that the photocycloaddition reaction rate is influenced by the configuration at C-3. Quenching experiments suggested that the major pathway upon interaction of **43** with $^1\text{O}_2$ is not the reaction but the quenching.

Further investigation demonstrated that the photocycloaddition reaction is also affected by the alkene geometry, as the (*E*)-isomers of **43b,c** produce MDB in higher ee's than the (*Z*)-isomers. For example, a 1:1 mixture of (*3R,4R*)- and (*3S,4R*)-(*Z*)-**43c** give (*R*)-MDB in $27 \pm 4\%$ ee, while the same diastereomer pair of (*E*)-**43c** gave an almost doubled ee value.⁶³ This chiral photoreaction was revealed to be sensitive to solvent and temperature, and (*R*)-MDB of 97% ee was obtained in CD_3OD at -70°C at 8% conversion.

Tung et al. investigated the photodimerization of 2-naphthoates **46a–g** with chiral ester auxiliaries.⁶⁷ Photodimerization of alkyl 2-naphthoates **46a–g** resulted in *anti*^{HH}-**47a–g** as main products. For substrates **46a–f** with α -chiral ester moieties, relatively high diastereoselectivities of up to 59% de were achieved. In contrast, substrate **46g** with a β -chiral auxiliary gave the photodimers in <5% de, revealing the critical role of the proximate chiral center. The de of photodimer **47** was also affected by the solvent used, as evidenced by the fact that *anti*^{HH}-**47** was given in –54% de (88% yield) in cyclohexane but in –44% de (83% yield) in methanol.

Sakamoto et al. reported a highly enantiodifferentiating cross-photocycloaddition of 2-alkoxyl-1-naphthamides **48** and **51** with 9-cyanoanthracene **49** in solution.^{68–71} In these naphthamides, the free rotation about the aryl-carbonyl bond is more or less hindered as a consequence of the steric bulk of the *N*-substituent and the enantiomeric atropisomers are conformationally fixed at low temperatures and in the solid state. In the case of **48a** and **48b**, the relatively compact amide group allows racemization to occur in solution at room temperature. The racemization half-lives of **48a** in THF are 11.8, 19.4, and 36.7 min at 15°C, 10°C, and 5°C, respectively, but can be elongated to 128.3 min by using a mixed solvent of MeOH and THF at 15°C, which may be rationalized by the increased bulk of the amide moiety solvated by methanol. Interestingly, naphthamide **48a** (R = Me) forms chiral crystals of *P*2₁2₁ space group, while **48b** (R = Et) gives racemic *P*2₁/*c* crystals. Photolysis of a cooled solution of crystalline **48a** and **49** gave cross-cycloadduct **50** of 95% ee in quantitative yield, achieving the memory of labile chirality. Naphthamides **51a,b** that carry proline methyl ester as a chiral handle were synthesized for

further investigating the chiral memory effect in diastereodifferentiating photocycloaddition. Bearing an (*S*)-proline moiety, amides **51a,b** adopt the (*S*, *aR*)-conformation in the crystals of $P2_1$ space group. The activation free energy required for the conformational transformation between the two diastereomeric isomers in solution was determined as 22.2–22.3 kcal mol⁻¹. Photocycloaddition of amides **51a,b** to **49** in solution at –20°C gave **52a** and **52b** in 63% and 53% de, respectively. However, the photoirradiation of the chiral crystals gave the same products in up to 100% de.

Achiral *N,N*-diethyl-4-coumarin-3-carboxamide **53** crystallizes in chiral space group $P2_12_12_1$, where the amide carbonyl is twisted almost orthogonally to the coumarin plane. The activation free energy for the racemization of **53** in solution varies in a range 20.5–22.4 kcal mol⁻¹, depending on the solvent used.⁷² The intermolecular [2 + 2] photocycloaddition of alkenes **54** to temporary chiral amide **53** performed by direct irradiation in methanol at –20°C gave **endo-55** and **exo-55** in 82% and 86% ee, respectively. However, the use of benzophenone as a triplet sensitizer afforded **endo-55a** of 98% ee and **exo-55a** of 97% ee in 99% combined yield. The lower ee observed upon direct irradiation was ascribed to the racemization of the starting amide accelerated in the singlet excited state. Using **54b** as substrate for the photocycloaddition to **53**, **endo-55b** was given as a sole product in 99% ee.

Inoue et al. have recently reported the wavelength control of diastereoselectivity of Paternó-Büchi reaction of **56a,b** by choosing the direct and charge-transfer (CT) band excitation.⁷³ The CT complex of **56a** with **57** has a modest binding constant of 0.04 M⁻¹ at 25°C. Direct excitation of **56** at 290 nm gave **58a** and **58b** in 64% and 71% de, respectively, while much lower de's of 4% and 22% were obtained upon CT band excitation at 330 nm, suggesting that the conventional exciplex and the excited CT complex do not share a common intermediate but have distinctly different structures and reactivities in the excited state. Intriguingly, the oppositely signed differential activation enthalpy change $\Delta\Delta H^\ddagger$ and entropy change $\Delta\Delta S^\ddagger$ were obtained for direct and CT excitations. The magnitude of $\Delta\Delta S^\ddagger$ is appreciably larger for the direct excitation than for the CT excitation, possibly due to the better stacked CT complex that is less flexible in the excited state than the exciplex.

Inoue et al. examined the photocyclodimerization of 2-anthracenecarboxylic acid (AC) in the presence of chiral templates **60** and **61**. Photocyclodimerization of AC gives four stereoisomeric dimers, that is, *anti*- and *syn*-*head-to-tail* (HT) dimers **59a** and **59b** and *anti*- and *syn*-*head-to-head* (HH) dimers **59c** and **59d**, of which **59b** and **59c** are chiral. The enantiodifferentiating photocyclodimerization of AC was firstly studied in organized media by using native γ -CD as chiral host.⁷⁴ The gastroprokinetic agent **60** and its epimer **61** were found to strongly bind AC by forming a nine-membered dual hydrogen-bonding motif between the prolinol's amino and hydroxyl groups.⁷⁵ One of the enantiofaces of AC was blocked by the 2-methoxybenzamide

moiety of **60** upon stacking complexation, and the photocyclodimerization of AC can occur only from the opposite side of bound AC. In the presence of chiral template **60**, photocyclodimerization of AC affords HT dimer **59b** in –36% ee and HH dimer **59c** in –40% ee in CH_2Cl_2 at -50°C . In contrast, epimer **61**, which forms an extended, rather than stacked, complex with AC leading to poor enantioselectivity (<3% ee). Detailed photophysical and photochemical studies of the system revealed that the ee is not simply determined by the ratio of diastereomeric *re*- and *si*-AC-**60** complexes but also affected by the relative lifetime of these diastereomeric complexes.⁷⁶ The *re*-complex has a lifetime of 3.7 ns, which is much shorter than that of *si*-complex (10 ns). The encounter complexes are proposed to have a perpendicular geometry, where electrostatic repulsion is minimized, and the enantioselectivity lies on the relative rotation of two perpendicularly contacted AC molecules. By taking the relative lifetimes of complexes into account, the relative population of the diastereomeric complexes was successfully calculated from the ee values of dimers.

Bach et al. examined a number of enantiodifferentiating intermolecular photoreactions in the presence of chiral templates **30**. When complexed by these chiral templates, one enantioface of the bound photosubstrate is shielded by the chiral template and the subsequent photoreaction occurs only from the unshielded face. Photoirradiation of aromatic aldehyde **62** yields dienol intermediates firstly as a result of intramolecular γ -hydrogen abstraction. The (*Z*)-dienol returns to the starting material quickly but the (*E*)-isomer has a longer lifetime to process a Diels–Alder reaction with a dienophile. The photoinduced cycloaddition of **62** to alkene in the presence of **30a** prefers the *exo* product **63** and furnishes photoproducts in up to 94% ee.⁷⁷

Intermolecular [4 + 4] photocycloaddition of 2-pyridinone to cyclopentadiene affords racemic **65** and **66** in a ratio of 2:3 in the absence of chiral template. However, the photocycloaddition in the presence of **30a** gave **65** and **66** in remarkable 84%–87% ee's.⁷⁸

6.3.1.3 Sensitized Photochirogenesis in Organic Solvent

An essential advantage of sensitized photochirogenesis over other photochirogenic strategies is the inherently “catalytic” nature of the chirality transfer process, which enables us to photochemically multiply the molecular chirality with a minimal amount of chiral sensitizer as is the case with catalytic or enzymatic asymmetric synthesis. On the other hand, the intermolecular chirality transfer process in the excited state is difficult to control or design and the enantioselectivity reported for sensitized photochirogenesis has not been very high in general until recently. Thus, as a modification or expansion of the concept of traditional chiral photosensitization via exciplex intermediate, a couple of inventions have been proposed to assure the chirogen–substrate interactions in the excited state, while keeping the “catalytic” nature. These include the selective excitation of the charge-transfer or other complexation-induced absorption emerged at longer wavelengths upon formation of chirogen–substrate complex in the ground state and the photoredox reaction–mediated by chiral donor or acceptor. In all of these strategies, it is essential that an appropriate wavelength should be chosen for selectively activating the chiral sensitizer, mediator, or complex derived therefrom while avoiding the direct excitation of substrate, and also that strong and intimate interactions should be maintained between chirogen and substrate for an appropriate period of time to effectively transfer the chiral information to the substrate in the excited state. In this context, the singlet sensitization via the Förster mechanism does not appear to be suitable for the chirality transfer in the excited state, since no steric interaction is expected to occur during the coupled energy transfer.

Photosensitized isomerization of 1,2-diphenylcyclopropane, the very first example of enantiodifferentiating photosensitization reported by Hammond and Cole, has been extensively investigated.^{79–82} However, the photoisomerization sensitized by conventional chiral sensitizers in solution affords *trans*-1,2-diphenylcyclopropane in only 10% ee at the best.⁸³

Inoue et al. investigated the sensitized enantiodifferentiating photoisomerization of cycloalkenes, which has now become a sort of benchmark test system for studying photochirogenesis.^{84–96} Representative examples include the *Z*-*E* photoisomerization of cyclooctene **67Z** and 1,3- and 1,5-cyclooctadienes **69ZZ** and **71ZZ** to the corresponding planar chiral (*E*)-isomers **68E**, **70EZ** and **72EZ**. A series of benzene(poly)carboxylates **73a–f** with a variety of ester groups were synthesized as chiral singlet sensitizers to explore the effects of internal and external factors on the enantiodifferentiating photoisomerization of cycloalkenes. By analyzing the behavior of ee obtained upon sensitized photoisomerization of cyclooctene **67Z** at various temperatures, they unequivocally revealed the essential roles of entropy in the critical enantiodifferentiating process occurring in an exciplex intermediate. Thus, the chiral sense of product **68E** was dramatically inverted by simply changing the reaction temperature in several cases.^{85–87} It was further demonstrated that the other entropy-related factors, such as solvation and hydrostatic pressure, also significantly affect the enantiodifferentiation process not only to increase the product's ee but also to switch the chiral sense of the product. Therefore, by optimizing these environmental factors, the enantioselectivity was enhanced up to 73% ee for **68E** and 75% ee for **72EZ**, although the enantioselectivity remained low at 14.3% ee for **70EZ**.⁹⁷

Bach et al. reported the chiral photocyclization of pyrrolidine-appended quinolone **75** mediated by chiral template **74a**, in which a hydrogen-bonding motif, the Kemp's acid derivative, was covalently grafted with a photoinduced electron transfer (PET) sensitizer, benzophenone.^{98,99} Upon complexation with the chiral template through dual hydrogen bonds, one of the enantiofaces of **75** is covered by the benzophenone moiety of **74a**. Photoirradiation of **74a** causes the electron transfer from the pyrrolidine nitrogen in **75** to the benzophenone in **74a**, which is followed by the migration of a hydrogen from the carbon α to nitrogen to the radical anionic benzophenone. The resulting pyrrolidyl radical attacks the *ipso*-carbon to form the spiro skeleton preferentially from the open face of quinolone, and therefore the photocyclization of **75** in the presence of 0.1 equivalent of **74a** gave **76** in 52%–64% yield with up to 70% ee.

For PET reactions, polar solvents are commonly employed for better stabilizing the generated radical ion pair and also discouraging the back electron transfer through the formation of solvent-separated or free radical ion pair. However, this is obviously disadvantageous for transferring the chiral information from sensitizer to substrate, lacking any intimate interaction between them. Inoue et al. proposed an interesting approach that circumvents this trade-off by performing the photochirogenic PET reaction with a polar saccharide-modified photosensitizer in nonpolar solvents. Thus, the PET process can be facilitated by the microenvironmental polarity around the sensitizer, while solvent separation is prevented due to the low bulk polarity of nonpolar solvent.¹⁰⁰ By applying this approach to the anti-Markovnikov addition of alcohol to 1,1-diphenyl-2-alkoxypropene **79** sensitized by chiral naphthalene(di)carboxylates **81–85**, they obtained photoadduct **80** in up to 58% ee for **82h**.

More recently, Bach et al. employed chiral template-sensitizer **74a,b** for the intramolecular [2 + 2] photocycloaddition of prochiral 4-(3'-butenyloxy)quinolone **77** to obtain tricyclic adduct **78a** and **78b**.¹⁰¹ In the presence of 0.1 equivalent of benzophenone-appended chiral template **74a**, cycloadducts **78a** and **78b** were given in a ratio of 75:25 with 39% and 17% ee, respectively. No reaction took place at temperatures lower than $-25^\circ C$, for which the relatively low triplet energy of the sensitizer would be responsible. However, xanthone-bearing template **74b** with a higher triplet energy of 310 kJ mol^{-1} and a more effective shielding group gave **78a** and **78b** in much higher 94% ee.

MacMillan et al. recently reported a photoinduced asymmetric alkylation of aldehydes **86**.¹⁰² The chiral reaction involves the addition of electron-deficient alkyl radical, formed via the reduction of alkyl bromide by photoredox catalyst $\text{Ru}(\text{bpy})_3^{2+}$, to an electron-rich enamine generated by the condensation of aldehyde **86** and organocatalyst **87**. The photoexcited $^*\text{Ru}(\text{bpy})_3^{2+}$ is thought to efficiently remove a single electron from a sacrificial quantity of enamine to provide the electron-rich $\text{Ru}(\text{bpy})_3^{2+}$, which electron transfers to alkyl bromide with an electron-withdrawing group (EWG) to furnish the electron-deficient alkyl radical. Attack of the alkyl radical to the enamine proceeds in a highly enantioselective fashion to eventually give the adduct, and therefore **88**, in high ee's of up to 99%. Due to the intensive absorption of $\text{Ru}(\text{bpy})_3^{2+}$, the photoreaction was readily initiated and efficiently underwent even by using a 15 W fluorescent lamp as a light source. In a common chiral photosensitization, sensitizer is covalently attached to a chiral substituent in order to ensure chiral environment for the sensitized photochirogenic process. In contrast, $\text{Ru}(\text{bpy})_3^{2+}$ was used as a sensitizer without a chiral substituent in this case, as the photogenerated alkyl radical reacts with the chiral enamine rather than aldehyde directly. Thus, **87** functions as an efficient chiral auxiliary for the diastereodifferentiating addition of alkyl radical generated photochemically.

The same photoredox organocatalysis strategy was employed in α -trifluoromethylation of aldehydes.¹⁰³ The photoinduced enantiodifferentiating α -trifluoromethylation of aldehydes **86** was carried out in the presence of chiral organocatalyst **87** and photocatalyst $\text{Ru}(\text{bpy})_3^{2+}$ or $\text{Ir}(\text{ppy})_2(\text{dtb-bpy})^+$. Employing **87** as chiral organocatalyst, the photoaddition of **86c** at -20°C afforded **89c** in 87% ee by $\text{Ru}(\text{bpy})_3^{2+}$ but 99% ee by $\text{Ir}(\text{ppy})_2(\text{dtb-bpy})^+$, implying a possible involvement of the photocatalyst in the enantiodifferentiating process. Exclusion of light from this protocol resulted in an almost complete loss of catalyst efficiency (<5% yield). Photoreaction of **86a–d** with different substituents sensitized by $\text{Ir}(\text{ppy})_2(\text{dtb-bpy})^+$ in the presence of **87** at -20°C gave α -trifluoromethyl ketones **89a–d** in >90% ee.

Yoon et al. reported that $\text{Ru}(\text{bpy})_3^{2+}$ serves as an excellent photocatalyst for the intra- and intermolecular anion radical-mediated [2 + 2] enone cycloadditions.^{104,105} For example, photoirradiation of a solution containing **90**, **91** and $\text{Ru}(\text{bpy})_3^{2+}$ with visible light for 4 h affords the [2 + 2] cross-cycloadduct **92** in 84% isolated yield, while direct irradiation of the mixture of **90** and **91** at 300 nm failed to produce any observable cycloadducts but isomers originated from E/Z isomerization of enone **90**. In this work, no attempt has been done to control the enantioselectivity, but an excellent diastereoselectivity for **92** was observed with dr >10:1 (>91% de).

6.3.2 Photochirogenesis in Chiral Ionic Liquid

Chiral solvents have been employed as a source of chirality for photochirogenic reactions. An inherent disadvantage of this strategy is the use of a large excess amount of costly enantiopure compound as chiral solvent. Despite the low chirogen efficiency and cost performance, the efficiency of photochemical chirality transfer is poor in general, with the highest ee values of <10%.¹⁰⁶

As a new medium for photochirogenesis, chiral ionic liquid, room-temperature molten salt, has been used recently. The use of chiral ionic liquid is beneficial not only from the environmental but also from

the photochirogenic viewpoints, since some chiral ionic liquids are readily available (or easily prepared), can be removed from the reaction mixture, and hence recyclable. The easy access to antipodal ionic liquids would be an additional benefit.

Armstrong et al. investigated the enantiodifferentiating di- π -methane photorearrangement of dibenzobicyclo[2.2.2]octatrienedicarboxylic acid derivatives **93a–c** to the corresponding tricyclic compounds **94a–c** in chiral ionic liquids **95a–d**.¹⁰⁷ Photoirradiation of methyl ester **93b** in chiral ionic liquids **95a–d** led to the formation of racemic **94b** without exception. In contrast, the photorearrangement of carboxylic acid **93c** in **95b** gave **94c** in modest 6% ee, while no enantiodifferentiation was observed upon irradiation in other three chiral ionic liquids. The observed enantioselectivity is possibly due to the interaction of the acid substrate with the ionic liquid. Interestingly, in the presence of added base, such as *N*-methylephedrine, *N,N*-dimethylbenzylamine and sodium hydroxide, the photorearrangement of **93c** performed in all of the chiral ionic liquids provided **94c** in appreciable enantioselectivities. Nevertheless, the chiral induction is considered to originate not from the added base but from the chiral medium, as the addition of antipodal *N*-methylephedrines gave similar ee values in the same ionic liquid and the antipodal chiral ionic liquid gave the antipodal product, irrespective of the chiral amines added. This may indicate that the added base simply facilitates the dissociation of **93c** to carboxylate for better interaction with chiral imidazolium cation.

Apart from the photochemical reactions, some photophysical properties have also been investigated in chiral ionic liquids. Enantiodifferentiating fluorescence quenching by intramolecular PET was studied in chiral ionic liquid.¹⁰⁸ The lifetime of *N*-methyl-2-pyrrolidinemethyl (*S*)-(6-methoxy-2-naphthyl) propionate was 8.9 ns in *D*-tartrate ionic liquid, but became 10% longer in *L*-tartrate ionic liquid. The observed differences in fluorescence lifetime and steady-state fluorescence quantum yield became more evident at higher temperatures.

6.3.3 Photochirogenesis in Supercritical Fluid

In contrast to conventional organic solvents, supercritical carbon dioxide (scCO₂) possesses several advantages, such as inflammability, low toxicity, low density, low viscosity, and low cost. Photochirogenesis in scCO₂ was firstly reported for the enantiodifferentiating photoisomerization

of cyclooctene **67Z** sensitized by chiral benzene(poly)carboxylates **73**.⁹³ Since the sensitized photoisomerization of **67Z** is highly sensitive to solvation,⁹² it is particularly interesting to examine the photoreaction near the critical point, where the solvent properties such as viscosity, density, and dielectric constant changed drastically in narrow ranges of pressure and temperature. Indeed, a sudden change of enantioselectivity was observed near the critical density ($\rho_c = 0.468 \text{ g/cm}^3$; $P = 9.8 \text{ MPa}$ at 45°C). The differential activation volume ($\Delta\Delta V_{S-R}^\ddagger = \Delta V_S^\ddagger - \Delta V_R^\ddagger$) obtained for the near-critical region ($-5.6 \text{ cm}^3/\text{mol}$) was much greater than that for the same photoisomerization performed in pentane ($3.5 \text{ cm}^3/\text{mol}$), suggesting that the transition-state structure and/or enantiodifferentiation mechanism in near critical (nc) CO_2 are completely different from those in scCO_2 and conventional organic solvents.

The scope of photochirogenesis in scCO_2 was expanded to bimolecular reaction systems through investigating the enantiodifferentiating polar photoaddition of alcohol to 1,1-diphenylpropene **79** sensitized by chiral naphthalenecarboxylates **81–85**.^{109–112} The reactivity and enantioselectivity were critically correlated by the bulkiness of the attacking agent, alcohol. Thus, the enantioselectivity increases with the size of alcohol and gives the best ee for 2-propanol, while the bulkiest *t*-butanol yields no adduct. For all the sensitizers, a large leap of ee was observed around the critical density at the narrow pressure range of 9–10 MPa, while the pressure dependence of ee is continuous in the subcritical region of $P < 9 \text{ MPa}$ and supercritical region of $P > 10 \text{ MPa}$.

The sudden leap of ee in the narrow pressure range transferring from the near-critical to supercritical state implies a significant difference in clustering mechanism and/or cluster structure between both states. Recently, the effect of entrainer (organic solvent added to scCO_2) on the intramolecular photoaddition of **96** in ncCO_2 and scCO_2 has been examined.¹¹² In organic solvents, the enantioselectivity is known to critically depend on the microenvironmental polarity around the exciplex intermediate, and the addition of a small amount of ether to methylcyclohexane appreciably enhances the ee of **97** as a result of the selective solvation. Hence, the effect of methanol clustering to sensitizer **82h** was examined in scCO_2 to reveal the appreciable bathochromic shift and band broadening induced by lowering the pressure from 10 to 9 MPa, which were accounted for in terms of the enhanced clustering of methanol to the saccharide moiety. In the photoaddition of methanol to **96** in the presence of **82h**, the differential activation volumes $\Delta\Delta V_{S-R}^\ddagger$ were determined as 60, 530, and $22 \text{ cm}^3 \text{ mol}^{-1}$ for the pressure regions 7.7–9, 9–10, and 10–18 MPa, respectively, which are much larger than those in organic solvents. The anomalously large $\Delta\Delta V_{S-R}^\ddagger$ value obtained near the critical density may reflect the dynamic nature and the density fluctuation of this critical region.

6.4 Photochirogenesis in Organized Media

6.4.1 Photochirogenesis in Nanosized Cavity of Zeolite and Mesoporous Silica

Zeolites are aluminosilicates with well-defined mesoporous structures.^{113,114} They are attractive as supramolecular hosts for photoreactions, being transparent to UV/Vis lights and possessing supercages, the size of which is tunable by changing the counteranions compensating the negative charge

of $[\text{AlO}_4]^{5-}$ tetrahedra. Indeed, the diastereodifferentiating photoreactions conducted in zeolite supercage show remarkable differences from those in homogeneous solution. Thus, photoirradiation of (*S*)-tropolone-2-methylbutyl ether **98** in hexane leads to the formation of a 1:1 mixture of diastereomers **99a** and **99b**, while the same photoreaction conducted in NaY zeolite affords **99a** in up to 68% de.¹¹⁵ In contrast, the photocyclization of **98** on silica gel surface gave **99a** without any diastereodifferentiation, confirming the important role of confinement played by the zeolite supercages.

Similarly, only negligible diastereoselectivities were observed upon photoirradiation of 2,2-dimethyl-(2*H*)-naphthalenone-4-carboxylates **100** either in hexane solution or on silica gel surface. In contrary, **101b** and **101c** were given in 57% and 47% de, respectively, upon photoirradiation of **100** in supercage of NaY zeolite.

The oxa-di- π -methane rearrangement of 2,4-cyclohexadienones-4-carboxylate and -carboxamide **102** in trifluoroethanol solution afforded **103** in a low de (<5%). However, **103b** and **103e** were formed in up to 59% and 73% de, respectively, when the photoreaction was carried out within NaY zeolite.¹¹⁶ Interestingly, the diastereoselectivity was switched to give the epimeric product by changing the zeolite host from LiY or NaY to KY, RbY or CsY, suggesting that the stereochemical fate is highly sensitive to the size of supercage and is tunable by the cation species in zeolites.

Diastereodifferentiating photoisomerization of chiral *cis*-2,3-diphenyl-1-benzoylcyclopropane derivatives **104** was examined in the supercage of zeolite. Photoisomerization of **104** is implemented through the C1–C2 or C1–C3 cleavage, the bond rotation about C2–C3, and the ring closure to diastereomeric *trans*-isomers.^{117,118} The photolysis of **104** in zeolite supercage led to much higher diastereoselectivity than that in organic solvent, and the *meta*- rather than *para*-substituted substrates consistently afforded higher de's of up to 71% for **104g**.^{119–121} Irradiation period and temperature were found to have only minor effects on the diastereoselectivity, probably due to the rigidity of zeolite supercage.

Direct and triplet-sensitized diastereodifferentiating photoisomerizations of chiral 2,3-diphenylcyclopropane-1 α -carboxylates **105** was investigated in LiY, NaY, KY, RbY, and CsY zeolites.¹¹⁷ Direct irradiation of **105a** adsorbed in zeolite gave **106a** and **107a** in up to 55% de. Photolysis of **105c** in homogeneous solution gave a low de of <5%, while the epimeric product was obtained in 50% de upon irradiation in zeolite. The stereochemical outcomes upon direct irradiation considerably differed from those from the triplet sensitization by 4-methoxyacetophenone,¹²² and the chiral auxiliaries possessing an aromatic or carbonyl substituent performed better than those with alkyl substituents.

Zeolite supercages are not inherently chiral and should be modified with chiral inductors for the use in enantiodifferentiating photoreactions. This is made possible by adsorbing chiral organic molecules into zeolite supercage or by replacing the inorganic cations in supercage with chiral organic ammonium ions. Indeed, several thermochemical asymmetric reactions have been carried out in chirally modified zeolite supercage prepared by using these methods.^{123–127}

The enantio- and diastereodifferentiating photoisomerization of diphenylcyclopropane derivatives in chirally modified zeolites were comprehensively studied in recent years.^{128–132} Upon direct excitation or triplet sensitization, the *cis*-to-*trans* photoisomerization of **108a** did not occur in the supercage of MY zeolite, probably due to the strong cation- π interaction that stabilizes the sandwich-type conformation of *cis*-diphenylcyclopropane. In contrast, the cations in supercage prefer to coordinate to the amide or

ester moiety of **108b–f**, and hence, the photoisomerization underwent smoothly to give the *trans*-isomer in a *cis:trans* ratio ranging from 12:88 to 58:42 at the photostationary state. By using ephedrine as a chiral inductor, photoisomerized product **109c** was obtained in 20% ee.^{122,133}

The enantiodifferentiating photocyclizations of tropolone derivatives **110** and pyridone derivatives **112** were performed in zeolites modified with chiral inductor such as ephedrine, norephedrine, and pseudoephedrine.^{134–141} The ee's of up to 69% were obtained for chiral photoproduct **111c** in the photocyclization of tropolone **110c** using ephedrine-modified zeolite.¹⁴⁰ Similarly, the enantiodifferentiating photocyclization of pyridone derivative **112e** using norephedrine-modified KY zeolite afforded cyclization product **113e** in 55% ee, demonstrating that the chiral organic compounds absorbed in the cavity of supercage can efficiently effect the chirality induction of the photosubstrate located nearby.

Turro et al. investigated the photolysis of racemic benzoin methyl ether **114** immobilized in chirally modified zeolites. The geminate radical pair derived from the Norrish type I (α -cleavage) reaction of **114** was shown to recombine with enantiodifferentiation in the chiral cavity, regenerating enantiomerically enriched starting material **114**. Upon photolysis in solution, **115a** and **115b** were formed as major product in 23% and 70% yield, respectively. However, **115c** became the major product (79% yield), when the photoreaction was performed in zeolite. Photolysis of racemic **114** in the NaY zeolite modified with diethyl tartrate gave **114** in 9.2% ee.¹⁴²

Di- π -methane rearrangement of benzonorbornadiene **116** is photochemically silent upon direct irradiation, but **117** is produced smoothly upon triplet sensitization.^{143,144} Photolysis of **116** in TIY zeolite, which is known to accelerate the intersystem crossing of adsorbed compound due to the heavy atom effect, afforded **117** efficiently.¹⁴⁵ By using (+)-ephedrine hydrochloride as a chiral inductor, the photolysis of **116** within the chirally modified TIY zeolite provided **117** in 14% ee.

Most of the photoreactions in chirally modified zeolites were done in the solid state and inevitably necessitate a stoichiometric, or even more, amount of chiral inductor. Inoue et al. tried to enhance the chirogen efficiency by using a substrate that is not adsorbed in zeolite and a catalytic amount of chiral sensitizer immobilized in zeolite. They comparatively studied the enantiodifferentiating photoisomerization of **67Z** sensitized by chiral sensitizer dissolved in homogeneous solution^{93,96} and the same photoisomerization mediated by chiral sensitizer-immobilized NaY zeolite performed in hexane suspension.¹⁴⁶ In homogenous solution, optically active 1-methylheptyl benzoate sensitizer afforded **68E** as a racemic mixture, while a modest ee of 4.5% was given in the photosensitization with NaY zeolite modified by methylheptyl benzoate.

Y-type zeolites were employed as confining media for the photooxygenation of chiral enecarbamates **43**, which is sensitive to the configuration around the double bond. In solution, the (*E*)-isomers consistently gave higher stereoselectivities than the corresponding (*Z*)-isomers. Moreover, the photoirradiation of chiral enecarbamates in zeolite in the absence of a $^1\text{O}_2$ -generating sensitizer led to very low conversions (<3%) with poor mass balances (<35%).⁶¹ Methylene blue was immobilized in zeolite as a $^1\text{O}_2$ -generating sensitizer for photooxidizing the enecarbamate.⁶⁴ Thus, photooxygenation of (*Z*)-(3*R*/S,4*S*)-**43c** in methylene blue-bearing NaY zeolite gave (*S*)-MDB in good yield and up to 80% ee, and (*Z*)-(3*R*/S,4*R*)-**43c** gave the same product in 71% ee, while (*E*)-(3*R*/S,4*R*)-**43c** afforded (*R*)-MDB in 63% ee in NaY zeolite modified with methylene blue. These results indicate that the stereoselectivity of the singlet oxygenation to give MDB relies on the configuration at the C4 position of the oxazolidinone moiety, and the zeolite provides a path favorable for the attack of $^1\text{O}_2$ to the C=C double bond of the substrate.

The intramolecular [2 + 2] photocycloaddition of 1-cyano-2-(5-methyl-2-oxa-4-hexenyl)naphthalene **118** was carried out in the supercages of chirally modified NaY zeolite.¹⁴⁷ Chiral inductors **120a–g** and substrate **118** were completely adsorbed by zeolite after stirring the suspension for 3 h in hexane, while only the adsorbed substrate was readily extracted from the zeolite by treating with acetonitrile. Irradiation of a cyclohexane slurry of dry NaY zeolite containing **118** and l-(+)-diethyl tartrate **120a** gave cycloadduct **119** in 10% ee, while other chiral inductors provided the same product in smaller ee's (<2%). The enantioselectivity was highly sensitive to the composition of zeolite, and the ee's of up to 15% were observed when NaY zeolites modified by enantiomerically pure amino alcohols **120b** and **120c** were used as chiral host.

(1R,2S)-*trans*-1,2-Diaminocyclohexane was covalently introduced to the surface of mesoporous silica MCM-41 to give a chiral mesoporous organosilica. The photoinduced di- π -methane rearrangement of 11-formyl-12-methyldibenzobarrelene **121** performed in these chiral mesoporous materials led to the formation of **122a** in 24% ee at a conversion of 11%.¹⁴⁸

Inoue et al. recently investigated the photocyclodimerization of 2-anthracenecarboxylic acid (AC) in γ -CD-modified mesoporous silica.¹⁴⁹ The mesostructured silica was prepared by co-condensing silica-modified γ -CD with triethoxysilane tethered to triblock polymer $\text{EO}_{20}\text{PO}_{70}\text{EO}_{20}$. The γ -CD-modified mesoporous silica thus prepared was shown to have a 2D-hexagonal structure with an average pore size of 3.4 nm, a surface area of 287.6 m²/g, and a total pore volume of 0.201 cm³/g. In aqueous solution, AC was adsorbed or complexed by the CD-modified mesoporous silica and gave the cyclodimers **59a–d** upon photoirradiation. In contrast to the results obtained upon photoirradiation of free AC in aqueous solution, where the HT dimers **59a** and **59b** were formed in >80% combined yield, the photocyclodimerization of AC in the mesoporous silica gave HH dimers **59c** and **59d** as major products in 73% combined yield. The HH preference is possibly due to the hydrogen-bonding interaction between AC's carboxylate and the walls of mesoporous silica as well as the modified microenvironment around γ -CD grafted on the walls of mesoporous silica. Photodimer **59c** was given in up to 45% yield in 24% ee by performing the photocyclodimerization of AC in γ -CD modified the mesoporous silica. On the other hand, much lower conversion of AC was obtained for the γ -CD modified mesoporous silica prepared by the postsynthesis method.

6.4.2 Cyclodextrin-Mediated Photochirogenesis

The enantiodifferentiating *Z–E* photoisomerization of (*Z*)-cyclooctene **67Z** included and sensitized by sensitizer-attached β -CDs represents one of the pioneering works in supramolecular photochirogenesis.^{150–156} Direct photolysis of solid-state complex of native β -CD and **67Z** with vacuum UV at 185 nm afforded (*E*)-isomer **67E** in negligible ee, revealing that the cavity of native β -CD is not efficient in transferring the supramolecular chirality to molecular chirality through a photochemical process.⁸² However, it was demonstrated that appropriate modification of β -CD with a chromophore can drastically improve the enantioselectivity of photoisomerization of **67Z** sensitized by the chromophore attached to CD. The sensitizer moiety is self-included and shielded in the CD cavity and therefore the energy transfer from the sensitizer to unbound **67Z** located outside the cavity is prohibited. Only **67Z** that is included within the CD cavity can efficiently form an exciplex with the sensitizer to undergo isomerization. Indeed, the first attempt of this concept with **123b** as supramolecular chiral sensitizer affords **67E** in 15% ee, which is remarkably higher than that obtained upon direct irradiation of **67Z**• β -CD complex.¹⁵² Later, the ee of **67E** was enhanced up to 24% ee by using 6-O-(methylphthaloyl)- β -CD **123c** as a chiral sensitizing host.¹⁵⁷

The photosensitizer structure appears to critically influence the stereochemical outcomes of the enantiodifferentiating photoisomerization. Thus, the photoisomerization of **67Z** sensitized by 6-*O*-(*m*-methoxybenzoyl)- β -CD **123g** afforded **67E** in 46% ee, which is the highest enantioselectivity ever reported with CD-based sensitizers.¹⁵³ The *ortho*- and *para*-analogues **123f** and **123h** gave much lower ee's of less than 15% under the identical reaction conditions.¹⁵⁴

It was found that the entropy factor does not play a significant role in photoisomerization of **67Z** with **123a–h** because of the rigid β -CD framework, which is in contrast to the significant entropy contribution observed in conventional photosensitization.^{85,96} However, when the photoisomerization of **67Z** is sensitized by *O*-permethylated 6-*O*-benzoyl- β -CD **67i**, which has a more flexible skeleton than nonmethylated CD derivatives due to the diminished hydrogen-bonding network at the secondary rim, the entropy-related factors become crucial as the enantioselectivity is strongly temperature-dependent.

Despite the apparent analogy to cyclooctene, (*Z,Z*)-1,3-cyclooctadiene **69ZZ** is much more difficult to photoisomerize to planar chiral (*E,Z*)-isomer **70EZ** in good ee. Thus, the enantiodifferentiating photoisomerization of **70ZZ** sensitized by naphthalene-substituted CDs **123k–m**¹⁵⁸ gave **70EZ** in modest enantioselectivities of up to 4.6% ee. Although only a faint effect of the entropy-related factors was observed with α - and β -CD-based sensitizer **123k** and **123l**, the entropy factor is much more effective for the photoisomerization mediated by γ -CD-based sensitizer **123m**, to which the more flexible framework of γ -CD is most likely attributed.

The intramolecular meta photocycloaddition of olefin to benzene ring is a highly effective approach for creating complex polycyclic molecules.^{159,160} Solid-state complexes of 4-phenoxy-1-butene derivatives **124** with β -CD, prepared by mixing the two components in hot aqueous solution, have host:guest stoichiometries of 2:1 for **124a** and **124c–e** but 1:1 for the others.¹⁶¹ Photolysis of the CD complexes of **124a**, **124b**, and **124e** gave only negligible enantioselectivities, while the rest of the complexes afforded modest enantioselectivities, with the highest ee of 17% for **125c**. It is deduced that one of the enantiotopic faces of the included benzene ring is better shielded by the CD walls when **124** is included in the β -CD cavity, favoring the attack of the vinyl from the opposite side.

Photolysis of chiral aryl ester **127** leads to the concerted elimination of carbon dioxide through a spiro-lactonic transition state to afford decarboxylation product **128**.^{162–166} The photodecarboxylation of enantiopure **127** in solution gave **128** with complete stereoretention (>99% ee). To investigate the relatively rigid and well-organized environment of CD on the concerted process, a racemic mixture of **127** was photolyzed in the presence of β -CD in aqueous solution. Up to 14.1% ee biasing (*R*)-enantiomer was given for **128**, indicating that one of enantiomeric **127** reacts faster than its antipodal isomer in the cavity of β -CD.

The [4 + 4] photocyclodimerization of AC with native γ -CD was firstly studied by Tamaki et al. in 1984.^{167,168} They demonstrated that the photodimerization quantum yield is significantly improved from 0.05 to 0.4 upon addition of γ -CD to the reaction mixture and the chemical yields of HT dimers **59a,b** are considerably increased at the expense of HH dimers **59c,d**. In contrast, β -CD forms a 2:2 complex with AC, which turned out to give exclusively achiral HT dimer **59a**. Inoue et al. reinvestigated the photoreaction in detail from the chirogenic point of view by using chiral HPLC for separating all of the six stereoisomers **59a–d**.⁷⁴ The binding behavior of AC with γ -CD was evaluated by spectral titration to give the stepwise association constants in aqueous solution at 25°C: $K_1 = 161 \text{ M}^{-1}$ and $K_2 = 38,500 \text{ M}^{-1}$. The much larger K_2 value was ascribed to the intimate contacts of two ACs with the CD walls in the 1:2 complex. Photocyclodimerization of AC in the presence of native γ -CD yielded HT dimer **59b** in up to 41% ee at 0°C, but HH dimer **59c** was given in <5% ee.

In order to improve the stereoselectivity of AC photocyclodimerization, a series of γ -CD derivatives have recently been designed and synthesized. Secondary rim-modified γ -CDs **130a–d** gave cyclodimer **59b** in ee's comparable to that obtained with native γ -CD, while 3^A-amino-3^A-deoxy-*altro*- γ -CD **130e** greatly enhanced the enantioselectivity. Such contrasting behavior was interpreted in terms of the electrostatic interaction between the cationic ammonium and anionic carboxylate as well as the distorted cavity due to the presence of the altrose unit.¹⁶⁹ The stereochemical outcomes of the supramolecular photocyclodimerization of AC with native and modified γ -CDs are sensitive to temperature and pressure. Hydrostatic pressure is rarely applied to the study of supramolecular systems but was found quite effective in controlling the supramolecular complexation and subsequent photochirogenic processes. In supramolecular photochirogenesis conducted in aqueous solutions, high pressure plays the primary role to discriminate the volume differences of two or more competing complexes, intermediates, and/or transition states and also the secondary role to reduce the freezing point of water down to –25°C at 200 MPa. Indeed, the ee of cyclodimer **59b** was enhanced up to 71%, when the photocyclodimerization of AC complexed with **130e** was carried out in aqueous solution at –21°C under a pressure of 210 MPa.

γ -CD derivatives **130g**, **131a–d**, and **132a–d** with two cationic groups on the primary rim were designed and synthesized for obtaining the HH cyclodimers as major products in the photocyclodimerization of AC.^{170,171} The two positively charged groups in the host were expected to attract two AC molecules to preferentially form the HH-oriented 1:2 complexes. Indeed, the yields of HH dimers were significantly improved by the use of the dicationic CDs, and the *anti/syn* ratio of HH dimers was gradually increased by increasing the interamino distance, exhibiting a good structure–function relationship in the supramolecular system. Up to 35% ee was given for **59c** by using host **132b** and optimizing the reaction temperature and solvent. On the other hand, the photocyclodimerization of

AC mediated by **130g** in aqueous methanol solution at a low temperature afforded **59c** of 41% ee in 42% yield, which is much higher than those obtained with **132a–d**, suggesting that two ammonium ions on a single flexible chain are more effective in manipulating the enantioselectivity. The yield and enantioselectivity of HH dimers were also significantly enhanced upon photolysis of a solid-state complex of AC with di-3,6-anhydro- γ -CDs **133a–d** with distorted cavities.¹⁷²

As the host structure was shown to greatly affect the stereochemical outcomes of photoreactions, a series of γ -CDs modified with various bridging substituents were synthesized to explore the effect of the aromatic cap on the photocyclodimerization of AC. Ditosylated γ -CD **134** gave the photocyclodimers in such yields and ee's that are comparable to those obtained with native γ -CD, indicating that the flexible capping does not appreciably alter the chiral environment of native γ -CD. Although diphenyl ether-capped γ -CD **136** and **137** gave **59b** in ee's lower than that obtained with native γ -CD, biphenyl-capped **135** afforded antipodal **59b** in a much enhanced ee of $\sim 56\%$. The seemingly tiny structural difference between **135** and **136** (by merely one oxygen) led to dramatic changes in chiral sense and ee of the photoproduct, unequivocally revealing the crucial role played by the rigid capping.^{173,174} γ -CDs **138** and **139** with a *p*-cresolbisbenzimidazole cap suffered pH-dependent conformational changes of the capping moiety with accompanying inversion of the enantioselectivity for HH dimer **59c** by changing the solution pH.¹⁷⁵

It was examined how and to what extent a bulky component located outside the cavity can affect the photoreaction occurring inside the cavity by using the supramolecular photocyclodimerization of α -CD-tethered AC **140** mediated by γ -CD and cucurbit[8]uril (CB[8]). Photolysis of **140** in water gave a mixture of α -CD-tethered AC dimers corresponding to **59a–d**, in which the HT dimers were favored. Photocyclodimerization of **140** included in native γ -CD resulted in γ -CD-wheeled rotaxane **141** in 68% yield at 210 MPa and -20°C , which was hydrolyzed to give HT dimer **59b** in 91% ee.¹⁷⁶ Strikingly, when

achiral CB[8] was used as a host, the major photoproduct was completely switched from HT to HH dimers and **59c,d** were obtained in 99% combined yield. It is thus demonstrated that a bulky group located outside the binding site can critically influence the reaction occurring inside.

Up to now, photosensitization is the only method to realize “catalytic” photochirogenesis. However, Inoue et al. have recently established a novel strategy for conducting catalytic photochirogenesis mediated by nonsensitizing metallosupramolecular hosts **143–145** that are coordinated with Cu^{2+} . Thus, in the presence of 0.1 equivalent of $\gamma\text{-CD-Cu}^{2+}$ complex, photocyclodimerization of AC in aqueous methanol solution at -50°C gave **59c** in 52% yield and up to 70% ee, which are the highest enantioselectivity ever reported for CD-mediated photochirogenesis.

6-(5-Cyanonaphthyl-1-carboamido)-6-deoxy- β -CD **146** was employed as an electron-accepting sensitizer for effecting the anti-Markovnikov photoaddition of methanol to 1,1-diphenylpropene **79a**.^{177,178}

The appended naphthalene component in **146** was demonstrated to perch laterally on the CD rim and shallowly included in the cavity in aqueous solution. The naphthalene fluorescence of **146** was efficiently quenched by **79a** in aqueous solution of low methanol contents but less efficiently in more hydrophobic solvents. Methanol adduct **80a** and water adduct **147** were competitively produced upon photosensitization of **79a** by **146** in aqueous solutions of different methanol contents, where **80a** is favored by a factor of 2.5 as a result of higher nucleophilicity of methanol. The enantioselectivity is generally low in solution of high methanol content, but is significantly improved by increasing water content to give 18% ee for **147** and 13% ee for **80a** in 10% methanol solution at -10°C . Being different from other supramolecular photochirogenesis with β -CD-based sensitizers, the enantioselectivity obtained with **146** was highly sensitive to the temperature change, and the ee value varied from -2.1% to 5.8% by lowering the reaction temperature from 45°C to -40°C in a 1:1 water–methanol mixture. By applying high pressure and low temperature, the ee of water adduct **147** was enhanced to 24%–26%.

Wu et al. reported the enantiodifferentiating photocyclodimerization of methyl 3-methoxyl-2-naphthoate **148** mediated by native γ -CD.¹⁷⁹ The photocyclodimerization of **148**–**150** is not a concerted but a stepwise process, requiring two photons to give [4 + 4] cycloadduct **149** as an intermediate, which is converted to cubane-like cyclodimer **150** upon absorption of a second photon. Native γ -CD was shown to form 1:2 host–guest complex with **148** with a binding constant of $6.7 \times 10^6 \text{ M}^{-2}$. The formation of the host–guest complex significantly improved the efficiency of the photocyclodimerization of **148**. Interestingly, the chirality delivery from γ -CD to the cube-like photodimer also occurs in a two-step fashion. Thus, the intermediate **149** was formed in only 39% ee, but the enantioselectivity of cube-like photodimer **150** was improved to 48% ee.

6.4.3 Photochirogenesis with Biomolecule

Biomolecules, such as protein and DNA, behave as naturally occurring chiral supramolecular hosts, possessing well-organized binding site(s) suitable for accommodating and orientating a variety of organic molecules in a stereospecific fashion. Photochemistry is environmentally benign and highly compatible with biomolecules, necessitating no harsh thermal activation or biohazardous heavy/transition metal catalyst. Thus, biomolecule-mediated photochirogenesis is normally carried out in aqueous solution under mild conditions. Nevertheless, the photosubstrate to be used in biosupramolecular photochirogenesis should be water-soluble at least to some extent.

Serum albumin is the most frequently used protein in photochirogenesis study, partly due to their high affinity to various organic compounds and commercial availability. Zandomeneghi et al. reported the first photochemical kinetic resolution of racemic 1,1'-binaphthol **151** with bovine serum albumin (BSA). Since the enantiomers of **151** showed distinctly different affinities to BSA and the bound species absorbed light at longer wavelengths, it was possible to selectively photodecompose the preferentially bound enantiomer. By applying such a strategy, they obtained (R)-(+)-**151** in 99.5% ee at 77% conversion upon photolysis of racemic **151** in the presence of BSA.^{180–182}

Inoue et al. investigated the enantiodifferentiating photoisomerization of cyclooctene **67Z** to **68E** sensitized by a series of nucleosides and nucleotides.¹⁸³ Photoisomerization of **67Z** sensitized by pyrimidine and purine nucleosides afforded **68E** in up to 5.2% ee at the photostationary state. By using calf thymus DNA (ctDNA) as chiral sensitizer, **68E** was yielded in –15.2% ee with an *E/Z* ratio of 0.008. The enantioselectivity was considerably reduced by carrying out the photoreaction at higher temperatures. Supramolecular interaction plays an important role in the enantiodifferentiating process, as indicated by the fact that the photoisomerization of **67Z** in 50% aqueous methanol, where ctDNA keeps its B-form but the supramolecular interaction between **67Z** and ctDNA is significantly reduced, gave **68E** in a negligible ee of –0.9%.

Inoue et al. have comprehensively studied the enantiodifferentiating photocyclodimerization of AC mediated by different proteins.^{76,183–186} Bovine serum albumin (BSA) was revealed to have four binding sites that accommodate one, three, two, and three AC molecules in the order of binding affinity.^{183,185} Somewhat unexpectedly, AC in the first unimolecular binding site gave dual fluorescence lifetimes of 4.8 and 2.1 ns, suggesting the existence of two binding modes that may differ in position and/or orientation. A much longer lifetime of 13.2 ns was obtained for ACs bound to the second site of BSA, and ACs bound to sites 3 and 4 showed a single lifetime of 15.8 ns, which is indistinguishable from that in bulk water. Nitromethane quenched the fluorescence of unbound AC, while ACs bound to sites 1 and 2 were nicely protected from the attack of nitromethane. Photocyclodimerization of AC in the presence of BSA dramatically switched the product distribution from HT for free AC to HH, affording *anti*-HH dimer **59c** in 40% yield. At the AC/BSA ratio of 3.6, *syn*-HT dimer **59b** was obtained in up to 38% ee in the presence of 18 mM nitromethane, while *anti*-HH dimer **59c** was given in up to 58% ee in the absence of nitromethane.¹⁸⁵

Human serum albumin (HSA), differing from BSA by only 26 (out of *ca.* 600) amino acid residues, exhibited totally different complexation, photophysical and photochemical behaviors with AC.^{187,188} Extensive spectroscopic studies on complexation behavior suggested that HSA possesses five different binding sites for AC. ACs complexed to the unimolecular binding sites 1 and 2 were unreactive due to the isolation from other ACs, but could be replaced by inhibitors, such as 4-iodobenzoate and warfarin, from which the exact positions of AC-binding sites 1 and 2 were pinpointed on the x-ray crystallographic structure. AC in site 3 was demonstrated to be moderately protected from the attack from species in bulk solution but still able to give chiral photoproducts with high ee.¹⁸⁶ In sharp contrast to the BSA case, the HT dimers were favored in the photocyclodimerization of AC in the presence of HSA. Significantly high ee's of 82% and 90% were obtained for **59b** and **59c**, respectively, upon irradiation of AC with HAS in aqueous buffer solution at 5°C.¹⁸³

6.4.4 Photochirogenesis in Liquid Crystal

Ishida et al. have studied enantiodifferentiating photocyclodimerization of AC and 1-anthracenecarboxylic acid **152** by using liquid crystals as chiral organized media for photochirogenesis.¹⁸⁹ The salt formed by mixing equimolar amounts of amphiphilic amino alcohol **154** and AC afforded liquid crystal (LC) of two

smectic phases with a transition temperature at 65°C and an isotropic phase at >100°C. The AC-containing LC was photolyzed and the resulting mixture was analyzed after the treatment with trimethylsilyldiazomethane to give the corresponding esters. The photoreaction in the smectic phases afforded the HH dimers exclusively. In particular, **59c** was obtained in 72% yield and up to 78% ee upon irradiation of AC with **154** at 30°C. The very high preference for the HH photodimers was attributed to the alignment of ACs in the LC. The packing mode of the liquid crystalline matrix was deduced to significantly influence the *syn/anti* selectivity, since the **59d/59c** ratio changed greatly in the different smectic phases. High combined yield (>98%) of HH dimers **153c** and **153d** was obtained also in the photocyclodimerization of **152** in the smectic phase, but a poor ee value of <2% was observed for chiral *anti*-HH dimer **153c**.

Tung et al. have examined the photocyclization of tropolone ethers **110a** in chiral inductor-modified lyotropic LCs prepared by dissolving chiral inductor in organic solvent following by the addition of sodium dodecyl sulfate (SDS) and water to the solution.¹⁹⁰ Lamellar LC phase was given by mixing pentanol, SDS, and water in a weight ratio of 1:1.5:1.5, while hexagonal LC was formed at a ratio of 1:6:9. Photoirradiation of **110a** in (1*R*,2*S*)-(–)- or (1*S*,2*R*)-(+)-norephedrine-doped hexagonal LC gave **106a** in up to 40% ee at –10°C, but a much lower enantioselectivity was given in lamellar LC phase. The good enantioselectivity was ascribed to the chelate complex of the substrate with the inductor formed through hydrogen-bonding interactions. Menthol, which has only one hydroxyl group and thus cannot form a chelate structure with the photosubstrate, gave only a poor enantioselectivity of <5% ee. The same lyotropic LCs were used for mediating the photochemical reduction and cleavage of cyclohexyl phenyl ketone **155** to chiral alcohol **156** *via* intermolecular hydrogen abstraction and to **157** *via* intramolecular hydrogen abstraction.¹⁹¹ The ratio of **156/157** was sensitive to the chiral inductor doped. Thus, a **156:157** ratio of 1:3 was given in the hexagonal LC phase in the presence of proline, while a 12:1 ratio was given in the presence of prolinol. Modest ee's of up to 5% were found for **156** in the photoreaction in norephedrine-doped LC.

Inoue et al. recently investigated the enantiodifferentiating photoisomerization of cyclooctene **67E** sensitized by different LCs, including lyotropic LCs of poly(γ -benzyl-L-glutamate) and difluorobenzene derivatives and thermotropic cholesteryl oleyl LCs.¹⁹² The as-employed LCs in general afforded only low enantioselectivities, but the lyotropic LCs of poly(γ -benzyl-L-glutamate) showed contrasting results in cholesteric and nematic mesophases. Photoisomerization in achiral difluorobenzene LC sensitized by doped chiral sensitizers suggests that the chiral spatial arrangement of the LC is not suitable to induce appreciable ee, but an optically active product can be photochemically derived from the molecular chirality of chiral sensitizer.

6.4.5 Photochirogenesis in Polymer

Ramamurthy et al. examined the effect of Nafion polymer on the diastereoselectivity of three different photoreactions, that is, the geometrical isomerization of *trans,trans*-2,3-diphenyl-cyclopropane-carboxylic acid derivatives **158a,b**, the electrocyclization of 2-oxo-1,2-dihydropyridine-1-acetic acid derivatives **159a,b**, and the oxa-di- π -methane rearrangement of dimethylnaphthalenone derivative **100c**.^{193,194} Nafion is a block copolymer of sulfonated tetrafluoroethylene, which forms a cluster of *ca.* 5 nm diameter with narrow channels (*ca.* 1 nm in diameter) interconnecting the clusters. In Nafion channels, the photochemical behavior of the aforementioned substrates was significantly altered from that observed in solution. Although these intramolecular photoreactions generally give a 1:1 mixture of diastereomeric products in organic solvent, the product's de varied from 5% to 21% upon photolysis in the nanoclusters of alkali ion-exchanged Nafion. Of particular interest, the product distribution was a critical function of the counteraction of Nafion. Na⁺ Nafion was found to give relatively high diastereoselectivity than Li⁺ Nafion. The moderately enhanced asymmetric induction may be ascribed to the combined effects of the different conformation of the reactant molecule within the ionic clusters of Nafion due to the cation–substrate interaction and the confinement provided by the Nafion's interior walls.

Inoue et al. investigated the photodecarboxylation of **127** in polyethylene (PE) films, including PE0, PE46, PE50, PE68, and PE74, as anticipated that the PE films can significantly influence both the ground-state conformations of photosubstrate and the diffusion rates of the intermediate(s) derived therefrom.¹⁶⁶ In all polymers examined, the near-perfect retention of stereochemistry (>98% ee) was observed for **128**. However, the ratio of **128/129** was highly dependent on the polymer employed. Two unstretched high-density PE films, PE68 and PE74, give **128** almost exclusively with a trace amount of **129**, suggesting that the cavities of these two PE films either force all of the **127** molecules to adopt *s-cis* conformations or prevent the escape of the radical pair to form **129**.

Polymer-supported catalysts have major advantages in product purification and catalyst reuse. Bach et al. used the chiral hydrogen-bonding agent immobilized on Wang resin and methoxypolyethylene glycol (MPEG) to examine the enantiodifferentiating intramolecular [2 + 2] photocycloaddition of **31**.¹⁹⁵ Photolysis of **31** in toluene in the presence of template polymer **160** gave **32** in an enantiomer ratio of 93:7 at conversions ranging from 24% to 31%, with **160** being recovered >90%. A much higher conversion of >96% was obtained with polymer **161** due to the good solubility of the polymer in toluene. Photoadduct **31** was given in an enantiomer ratio >95:5 and the chiral template was recovered >97%, when **161** was used as template.

6.4.6 Photochirogenesis in Other Organized Media

Fujita et al. reported the asymmetric [2 + 2] photocycloaddition of **162** to **163** within the cage of metal-mediated self-assembly **165** and **166**. Photochemical and thermal reactions carried out in the confined M_6L_4 cages led to remarkably acceleration and significantly high selectivity.^{196–198} In hosts **165** and **166**, chiral ligands are coordinated to the cage peripheries to provide the chiral environment. Up to 50% ee was obtained for **164b** in the photocycloaddition mediated by **165b**.¹⁹⁹ This study demonstrates that significantly chiral environment can be induced by the peripheral chiral auxiliaries located outside the cage.

Inoue et al. reported the photoisomerization of **67Z** in homochiral metal–organic POST-1 nanopores, which was composed of tartaric acid derivative **167** and zinc nitrate.^{156,200} Photoisomerization of **67Z** sensitized by POST-1 give **68E** with a modest ee of 5.4%, which is comparable to that observed in the photoisomerization of **67Z** sensitized by **168** (4.9% ee). The low enantioselectivity is possibly due to the large chiral channel of POST-1, which has a diameter much larger than the size of **67Z** and therefore is inefficient to constrain the movement of **67Z**.

Diastereodifferentiating photoreactions of **170**, **171**, and **173** mediated by octa acid **169**, which forms capsule-like structure through self-aggregation, were investigated by Ramamurthy et al.^{201,202} Photolysis of **170a–d** in acetonitrile gave cycloadducts in de less than 2%. However, in the presence of octa acid **169**, the diastereoselectivity was greatly improved. Up to 92% de was observed in the photoreaction of **170b**. Controlling free space and rotational freedom of photosubstrate in the capsule was deduced to be crucial in deciding the efficiency of chirality transfer. Moderately diastereodifferentiating photoreactions of **171** and **173** were observed when complexed to the synthetic cavitand **169**. Photoreaction of **171** and **173** in the presence of octa acid yielded **172** in 35% de at 298 K and **174** in 36% de at 178 K.

Shinkai et al. have studied the photocyclodimerization of AC in the gel formed by mixing D-alanine derivative **175** bearing 3,4,5-tris(*n*-dodecyloxy)benzoylamide moiety and nonpolar solvents such as cyclohexane.²⁰³ HH photodimers **59c** and **59d** were exclusively formed by performing the photocyclodimerization of AC in the gel thus formed. However, only poor ee of less than 10% was observed for chiral HH dimer **59c**.

6.5 Photochirogenesis in Single Crystal

Photochirogenesis in single crystal may be divided into three categories in terms of the chiral source employed, that is, chiral auxiliary introduced to photosubstrate, co-crystallization of achiral photosubstrate with chiral inductor, and chiral crystal formed from achiral photosubstrate. In this section, we will concisely introduce only the recent progresses in the solid-state photochirogenesis in single crystals. For bimolecular photoreactions in crystalline state, readers are directed to [Chapters 12 and 13](#) of Ref. [7].

The chiral auxiliary strategy is commonly employed in solution-phase photochirogenesis. At present, there are only several reports concerning the asymmetric induction by chiral auxiliary tethered to phototransformer in the crystalline state. Ramamurthy et al. compared the Yang photocyclizations of a series of α -oxoamides **176** performed in solution phase and crystal.^{204,205} Photoirradiation of α -oxoamide in solution led in general to poor chemo- and diastereoselectivities, affording a mixture of β -lactam and oxazolidinone with negligible de's for the former product. Interestingly, β -lactam was exclusively obtained upon photoirradiation of **176** in the crystalline state, and the de's as high as >80% were obtained for all of the α -oxoamide crystals at conversions <20%. In most cases, the de became lower upon prolonged irradiations, possibly due to the distortion or collapse of the original crystal structure caused by photoreaction. Significantly, the photolysis of crystalline **176a** quantitatively gave the corresponding β -lactam in 100% de even after 100% conversion.

For photosubstrates without any covalently bonded chiral auxiliary, co-crystallization with chiral inductor may be a method of choice for efficient photochirogenesis. Scheffer et al. investigated the solid-state photochirogenesis of a series of aryl ketones **178** co-crystallized with various chiral inductors.^{206–208} In solution, all of 4-carboxyphenyl cycloalkyl ketones **178a–c** gave the corresponding Yang cyclization product **179** upon irradiation. However, the photoreactivity turned out to be critically dependent on the size of cycloalkane ring in **178**. Thus, co-crystals of **178a** ($n = 0$) with chiral amines did not show

any photoreactivity in the solid state, while co-crystals of **178c** ($n = 2$) with chiral amines underwent the Norrish type I cleavage but no Yang cyclization upon irradiation. Only co-crystals of **178b** ($n = 1$) yielded cyclobutanol **179b** in the solid-state photoreaction. Of ten chiral amines examined, four gave **179b** in >90% ee. The salts of (*R*)-(-)-1-aminoindan and (*S*)-(-)-1-(*p*-tolyl)ethylamine afforded essentially the quantitative ee at 100% conversion. The distance between the carbonyl oxygen and one of the enantiotopic γ -hydrogens in the co-crystal of **178b** was shown to be 2.7 ± 0.2 Å, nicely satisfying the requirement for the Norrish type II reaction.

A series of *endo*-7-benzoylnorbornene derivatives **180** were photolyzed in co-crystals with various optically pure amines.²⁰⁹ In solution phase, retro-Claisen photorearrangement dominated the reaction to yield *cis*-fused dihydrofuran derivatives **181** in excellent chemical yields. Chiral crystals were given for **180i** by forming a salt bridge between the *para*-carboxylic substituent and chiral amine. The use of (*R*)- and (*S*)-1-phenylethylamine as chiral inductors led to the formation of antipodal dihydrofuran **181b** in ee as high as 95%. The ee of photoproduct decreased with increasing conversion, presumably due to the breakdown of the crystal lattice as the photoreaction proceeded.

Photoirradiation of *cis*-bicyclo[4.3.0]non-8-ylacetophenone **182** exclusively gave chiral *cis*-3a,4,5,6,7,7a-hexahydro-1H-indene **183** via the Norrish type II reaction both in solution and in the solid state.²¹⁰ The yields of **183** obtained upon irradiation of co-crystals of **182** with chiral amines **184a-e** were comparable to those obtained in solution, but the ee's were not very high ($\leq 44\%$).

Solid-state photolysis of co-crystals of **185** with optically pure amines, such as 1-phenylethylamine, 1-cyclohexylethylamine, 2-phenylpropylamine, and 1-(*p*-tolyl)ethylamine, afforded cyclobutanols **186** in good yields.²¹¹ Up to 96% ee was obtained at 22% conversion in the photolysis of co-crystal of **185** with 1-(*p*-tolyl)ethylamine at -40°C . A prolonged irradiation only slightly reduced the ee to 92% at 91% conversion.

Achiral compounds occasionally crystallize in chiral space groups, which can be transferred to molecular chirality and preserved in the photoproduct obtained upon irradiation. This strategy, not necessitating any chiral source and hence sometimes called absolute asymmetric synthesis, may provide chiral photoproducts with high enantioselectivity.⁷⁰ However, not all achiral compounds can form chiral crystals and usually crystals of both enantiomorphs may be formed in a given batch of crystals, although it is not uncommon that crystals of the same chiral sense are preferred upon careful crystallization. Also, the chiral sense of obtained crystal is difficult to predict. It usually needs to consult x-ray crystallographic analysis to determine whether the crystal is in a chiral form or not. With careful precautions, solid-state CD may be used as a convenient alternative tool to check the crystalline chirality.

Koshima et al. investigated the photocyclization of isopropylbenzophenone derivatives employing the co-crystallization approach.²¹² Three chiral salt crystals of carboxylic acid derivatives **187** with achiral amines were prepared by spontaneous crystallization. Photoirradiation of salt **187** at $>290\text{ nm}$ led to a single crystal-to-single crystal transformation to a mixture of hydrogen-abstraction photoproducts. Three optically active products **190**, **191**, and **192** were given in a 6:3:1 ratio with ee's ranging from 78% to 87%. Interestingly, irradiation of the same crystal at 350 nm afforded the cyclopentanol **190** as the sole product, but the mechanism for the wavelength-dependent behavior is not yet clear. In contrast, photoirradiation of chiral crystals of salts **188** and **189** afforded the corresponding cyclobutanols in ee's $<10\%$.

Irie et al. investigated the chiral co-crystal of diarylethene **193** with octafluoronaphthalene **195**.²¹³ Recrystallization of a 1:2 mixture of **193** and **195** in hexane afforded chiral monoclinic crystals containing **193** and **195** in 1:2 ratio. Photoirradiation of the chiral co-crystal gave (*R,R*)-**194** from the crystal of (*P*)-helical conformer and (*S,S*)-**194** from that of (*M*)-helical conformer both in >99% ee at conversions <11%. The significant enantioselectivity was ascribed to the naphthalene–octafluoronaphthalene stacking that was not greatly affected during the photochemical conversion.

6.6 Conclusions

In this chapter, we reviewed the recent development in photochirogenesis, a field that is relatively new and still rapidly growing, in terms of the reaction media adopted. The novel intriguing findings in unconventional media, such as scCO_2 , ionic liquids, liquid crystals, and other well-confined host cavity, started to unveil their unique properties and great potentials. The importance of highly ordered media for efficiently manipulating photochirogenic process is underscored by the significant enantioselectivities observed for the photoreactions performed in chiral liquid crystals. Chiral ionic liquids, which are not sufficient from the viewpoint of chiral-source efficiency alone, afforded only low optical yields in the limited attempts, but may become attractive chiral media from the green chemical point of view in the future, when further experimental attempts and mechanistic considerations can improve the stereochemical outcomes. The observation of the rapid leap of enantioselectivity in the near-critical region of scCO_2 is unprecedented and needs further clarifications of the effects of density fluctuation on photochirogenesis.

The chiral auxiliary strategy has met a considerable success. However, the consumption of equimolar amount of chiral source and the synthetic labor in covalently attaching the chiral auxiliary to photosubstrate and removing it after photoreaction reduces the value of the method to some degree. Photochirogenesis with chiral crystal is an attractive approach to optically active compounds without using any chiral source and often gives significantly high stereoselectivities, is limited to those

photosubstrates that crystallize in chiral space group, which is however difficult to predicate. The use of three-dimensionally well-organized chiral supramolecular hosts appears to be a highly efficient and promising strategy for inducing high stereoselectivity through the confinement of guest substrate in chiral supramolecular host cavity by manipulating the multiple noncovalent interactions.

Catalytic photochirogenesis is one of the most intriguing and challenging tasks in this area. Photochirogenesis with a catalytic amount of chiral source has been realized by enantiodifferentiating photosensitization, where only the excited-state interactions between chiral sensitizer and substrate contribute to the stereochemical outcomes. However, recent development in supramolecular chemistry provides another possibility to achieve a photochirogenic reaction with a catalytic amount of supramolecular chiral source at an accelerated rate through complexation of photosubstrate with chiral host.

Obviously, photochirogenesis has left its infancy, but is still rapidly growing and far away from maturity with many important aspects to be uncovered. The major tasks in this challenging area include the enhancement of chemo- and stereoselectivity in general and the achievement of catalytic photochirogenesis through supramolecular methodologies, for both of which interdisciplinary approaches would be most useful.

7.1 Introduction

While enantioselective reactions can, in the broadest sense, be understood as reactions in which enantiomerically pure compounds are produced, this section will be mostly concerned with reactions in which a new element of chirality is created from achiral starting materials. Auxiliary-induced diastereoselective reactions are therefore not covered by this review. Due to the increasing importance of helically and axially chiral compounds, we have, however, added a section on chirality transfer and chiral memory phenomena. In general, emphasis was put on recently reported work ideally with a synthetic relevance. Previous reviews on the topic have appeared in journals¹ and in books, for example, in Volume 11 of the *Molecular and Supramolecular Photochemistry* series,² and the reader is referred to Chapter 61 in the second edition of this handbook³ as a guideline to older reviews about stereoselective photocycloaddition reactions. Recent reviews on photochemical reactions in total synthesis^{4,5} might be useful for those interested in the preparative aspects of photochemistry. In addition, two chapters in this handbook, on photochemistry in confined media ([Chapter 11](#)) and on photochirogenesis ([Chapter 6](#)), deal with closely related topics. Finally, it should be mentioned that this account deals exclusively with solution-phase photochemistry.

7.2 Asymmetric Induction by Small Molecule Chiral Templates

When prochiral compounds are used as starting materials, a chiral environment is required to induce asymmetry. Chiral templates or complexing agents associate with a substrate via multipoint, noncovalent interactions, and complexation provides a chiral environment for the reaction to occur. If no catalytically active reaction center is present in such a template, the template must be used in stoichiometric or even superstoichiometric

quantities (Section 7.2.1). If, however, the complexation is combined with an energy or electron transfer from or to the template, it is possible to use these templates substoichiometrically (Section 7.2.2).

7.2.1 Stoichiometric Reagents

Several chiral templates that are used in stoichiometric amounts to induce enantioselectivity in photochemical reactions have been reported and are depicted in Scheme 7.1 (1–5). Each possesses a number of donor and acceptor sites for hydrogen bonding to the appropriate substrates.

The [4 + 4]-photocyclodimerization of anthracene derivatives is a popular target system for the study of template-mediated enantioselective reactions (Scheme 7.2) and will be referred to a number of times during this chapter. When the anthracene core is asymmetrically substituted, four dimeric products are possible (7–10), two of which are chiral (7 and 8). It should be noted that the absolute configurations of dimers 7 and 8 have not been determined in any example discussed in this chapter and therefore the “+” and “–” notation given to these compounds refers only to the order of elution from the HPLC column.

Inoue and coworkers have reported that irradiation of 2-anthracenecarboxylic acid (6) in the presence of chiral template 1 afforded chiral dimers “–”-7 and “–”-8 in enantiomeric excesses (*ee*) of up to 49% and 43%, respectively.^{6,7} NMR studies showed that template 1 binds anthracene 6 through a dual hydrogen-bonding motif incorporating the carboxylic acid and the hydroxymethylpyrrolidine moieties. Coordination of compound 6 to the chiral template leads to the formation of a pair of diastereomeric complexes where either the *re*- or the *si*-face is shielded by the methoxybenzamide moiety, which blocks the approach of the second

SCHEME 7.1 Structures of chiral templates, 1–4, which are used in stoichiometric amounts to induce enantioselectivity in photochemical reactions.

anthracene molecule. Circular dichroism was used to prove that while bound to template **1**, anthracene **6** is in a chiral environment. However, further studies indicated that the enantioselectivities observed were not determined solely by the relative amounts of the two diastereomeric complexes in the ground state, but also depended on their relative excited-state lifetimes. Specifically, the *re*-complex, which was determined to have the shorter singlet excited-state lifetime, was found to produce lower *ee* values than the corresponding *si*-complex. This is the first example, in which the combination of the ground- and excited-state properties of a host–guest complex has been invoked to explain the enantioselectivities observed for the reaction.

Functionalized TADDOL derivatives, such as **2** (Scheme 7.1), have also been used as chiral mediators for enantioselective photocycloaddition reactions.^{8,9} Enantioselective [3 + 2]-cycloaddition of 3-hydroxyflavone **11** and methyl cinnamate was achieved in the presence of TADDOL **2** affording cycloadduct **13** in 58% yield (Scheme 7.3).⁸ The enantioselectivity of the reaction was determined following base-induced rearrangement and reduction of compound **13** and found to be up to 89% *ee*.

On irradiation, oxidopyrylium betaine **12** is generated by excited-state intramolecular proton transfer (ESIPT). Previous studies on racemic material¹⁰ had revealed that a polar solvent such as methanol is required to facilitate this process via double proton transfer. In contrast, the enantioselective variant is conducted in apolar solvents, with compound **2** (Scheme 7.1) having the dual role of imparting chiral information and facilitating ESIPT. Both the aryl substituent (Ar) and the ketyl side chain (R) of compound **2** (Scheme 7.1) were shown to be important for generating enantioselectivity as some substitution patterns resulted in the TADDOL derivatives adopting conformations in which hydrogen bonding to the substrate is no longer possible. It is thought that enantioselectivity is achieved by hydrogen bonding of the electron-rich phenoxide oxygen of betaine **12** to template **2**, resulting in shielding of one of the enantiotopic faces of the substrate. This reaction was successfully applied in the total synthesis of rocaglamide natural products; for example, rocaglaol (**14**) was obtained in three steps from cycloadduct **13** and in 96% *ee* following recrystallization.

Chiral lactam **3** (Scheme 7.1) has been used to induce asymmetry in a variety of photochemically promoted processes including Diels–Alder reactions, [6 π]-cyclizations, [4 + 4]-photocycloaddition reactions, intra- and intermolecular [2 + 2]-photocycloaddition reactions, and Norrish–Yang cyclizations.¹¹ Template **3** possesses a lactam binding site for coordination of amide or lactam substrates and a sterically demanding backbone that shields one of the enantiotopic faces of a bound, prochiral substrate. In order to maximize substrate–template association, the reactions are typically run at low temperature in nonpolar solvents. Due to the bulk of the tetrahydronaphthalene shield, self-association of enantiomerically pure

SCHEME 7.3 Enantioselective [3 + 2]-photocycloaddition of photochemically generated oxidopyrylium betaine **12** and methyl cinnamate to give adduct **13**, which was subsequently transformed into rocaglaol (**14**).

template **3** is effectively 0. This allows the use of an excess of template and in most cases the reactions are run in the presence of 2.5 equivalents of compound **3** in order to maximize template–substrate association and minimize substrate self-association. The complexing agent is stable under irradiation at $\lambda \geq 300$ nm and in most cases can be recovered in yields >90% by simple column chromatography. An account of the early successes achieved using this chiral complexing agent was included in the previous edition of this book,³ so this section will serve only to update the reader of progress that has been made since 2002.

Photochemically generated *o*-quinodimethane **16** was shown to undergo a highly enantioselective Diels–Alder reaction with a number of dienes in the presence of template **3** (Scheme 7.4).^{12,13} Enantiomeric excesses of 91%–94% *ee* were obtained for the major diastereomer even when only 1.2 equivalents of the template were used. With increasing template concentrations (up to 2.5 equivalents) selectivities of up to 97% *ee* could be achieved. The simple diastereoselectivity was dependent on the dienophile used with diastereomeric ratios (*dr* = *endo*/*exo*) ranging from >95/5 (methyl acrylate) to 25/75 (acrylonitrile).

This level of enantioselectivity is the best that has been achieved to date using template **3**, which can be explained in terms of differences in template-binding affinity of the product relative to the substrate. Titration studies indicated that the product has only weak association with the template and, as a result, the ratio of free template to starting material increases as the reaction progresses. This was supported by the observation that the enantioselectivity improved with increased conversion.

Investigations continue to explore the scope of substrates that can be used in [2 + 2]-photocycloaddition reactions with template **3**. 4-(2'-Aminoethyl)quinolones undergo enantioselective inter- and intramolecular photocycloaddition reactions (70%–92% *ee*) with unsymmetrically 1,1-disubstituted olefins to generate two adjacent quaternary centers.^{14,15} This reaction was successfully employed in an enantioselective total synthesis of the indole alkaloid (+)-meloscine (**22**).¹⁶ Intermolecular [2 + 2]-photocycloaddition of the silylenolether derived from methyl pyruvate to quinolone **18** gave, after purification by chiral HPLC, the enantiomerically pure product **19**. Subsequent retro-benzilic acid rearrangement, presumably via intermediate **20**, afforded the tricyclic product **21**, which was further elaborated to the target natural product (**22**) (Scheme 7.5).¹⁷

Alkenyl-substituted 5,6-dihydro-1*H*-pyridin-2-ones have recently been investigated as substrates for enantioselective intramolecular [2 + 2]-photocycloaddition reactions (Scheme 7.6). Upon irradiation at $\lambda = 254$ nm, and under standard conditions (–60°C to –75°C, nonpolar solvent), these substrates underwent

SCHEME 7.4 Enantioselective Diels–Alder reaction of photochemically generated *o*-quinodimethane **16** and dimethylfumarate to afford cycloadducts *endo*- and *exo*-**17** (*dr* = *endo*/*exo* = 83/17), in 96% *ee* and 84% *ee*, respectively.

SCHEME 7.5 Total synthesis of the melodinus alkaloid meloscine (**22**), involving an enantioselective [2 + 2]-photocycloaddition of quinolone **18**.

SCHEME 7.6 Enantioselective intramolecular [2 + 2]-photocycloadditions of dihydropyridin-2-ones **23**, **24**, **27**, and **28**.

diastereo- and regioselective [2 + 2]-cycloadditions to afford the corresponding cyclobutane products in moderate to good enantioselectivities (34%–85% *ee*). A large difference in reaction rate and enantioselectivity was observed depending on the nature and position of the tether. Substitution in the 4-position (**23,24**) afforded products with disappointingly low enantioselectivity.¹⁸ The reaction of compound **23**, possessing an all carbon tether, was complete within 6 h affording cyclobutane **25** in only 34% *ee*. In contrast, the oxygen-substituted substrate (**24**) showed promising enantioselectivity after 3 h (75% *ee*) but delivered only 6% conversion. Upon continued irradiation the enantiomeric excess of product **26** decreased, which is thought to be due to decomposition of the complexing agent, and complete conversion was never achieved.

Better results were obtained with the 3-substituted analogues (**27,28**).¹⁹ A significant increase in enantioselectivity was observed for compound **27** and improved reaction rates resulted in complete conversion after only 4 h, even for compound **28**, which possesses an oxygen-containing tether. It was

proposed that the differences in reactivity and enantioselectivity exhibited by these 5,6-dihydro-1*H*-pyridin-2-one derivatives are due to a combination of binding affinity, substrate shielding, and conformational aspects in the reaction intermediates.

Modifications to both the shield moiety and the binding site of chiral complexing agent **3** have also been reported. The nor-analogue (**5**, Scheme 7.1), which possesses a γ -lactam rather than a δ -lactam binding site, was prepared and employed in the [2 + 2]-photocycloaddition of 3-substituted 5,6-dihydro-1*H*-pyridin-2-ones (Scheme 7.6).¹⁹ Although there was little difference observed in the enantiomeric excesses obtained for substrates possessing all carbon tethers (compound **29** was obtained in 85% *ee* with template **5** compared to 84% *ee* with template **3**) a significant increase in enantioselectivity was achieved for cycloadditions involving oxygen-tethered substrates such as **28**. Immobilization of template **3** on a polymeric support was investigated as a way to simplify and optimize its recovery and reuse.²⁰ Methoxypolyethylene glycol (MPEG) bound template (**4**) provided high conversions and enantioselectivity, under the standard irradiation conditions, for the [2 + 2]-photocycloaddition reaction of 4-allyloxyquinolone. Furthermore, the template was easily recovered from the reaction mixture in yields of 97%–99% by precipitation and filtration.

7.2.2 Catalytic Reagents

Enantioselective catalysis in templated photochemistry is possible if the reaction proceeds more rapidly in the bound complex than in the unbound substrate. The photochemical reaction may be accelerated either by energy or electron transfer, but in either case in order for the reaction to be both enantioselective and catalytic direct excitation of the substrate must be completely avoided. Furthermore, the lability of the system must be such that the substrate remains bound while the reaction is taking place but then the product is released to allow the catalyst to bind a new substrate.

To date, only a few distinct catalytic reagents, **31**–**33** (Scheme 7.7), have been reported that have the ability to induce asymmetry in photochemical reactions via hydrogen bonding. Each possesses a combination of a binding motif in a chiral environment and a sensitizer moiety able to accelerate a photochemical reaction by electron or energy transfer.

Catalytic, enantioselective photoinduced cyclization of quinolone **34** was achieved using chiral lactam **31**.²¹ Upon irradiation of the host–guest complex, the benzophenone moiety accepts an electron from the bound substrate via photon electron transfer (PET). The benzophenone shield then serves to ensure that intramolecular cyclization of the resultant diradical can only occur from one face of the prochiral substrate. 30 mol% of catalyst afforded product **35** in 64% yield and 70% *ee* (Scheme 7.8).

Chiral template **31** was subsequently investigated as a chiral sensitizer for the intramolecular [2 + 2]-photocycloaddition of quinolones.²² In this case the benzophenone moiety accelerates the rate of reaction by triplet energy transfer rather than PET. Irradiation of quinolone **36** at $\lambda = 366$ nm in the presence of 10 mol% of catalyst **31** afforded compounds **37** and **38** in 39% and 17% *ee*, respectively. The low enantioselectivity was attributed to the relatively low triplet energy and short wavelength absorbance

SCHEME 7.7 Structures of catalytic chiral templates, **31**–**33**, employed in enantioselective photochemical reactions.

SCHEME 7.8 Enantioselective PET catalysis in the cyclization of quinolone **34** to product **35**.

of the benzophenone moiety. Successful triplet sensitization requires that the triplet energy of the sensitizer be significantly higher than the triplet energy of the substrate to allow rapid energy transfer. In catalyst **32** the benzophenone shield is replaced by a xanthone chromophore, which better fulfills these criteria. Xanthone **32** proved to be a far superior catalyst for the [2 + 2]-cycloaddition of quinolone **36**, affording photoproducts **37** and **38** in up to 90% ee with 5 mol% catalyst loading. The enantioselectivity could be improved to 94% by increasing the catalyst loading to 20 mol% (Scheme 7.9).

The proposed catalytic cycle is depicted in Scheme 7.10. Catalyst–substrate complex (**32:36**) formation is achieved via two hydrogen bonds. Irradiation of the complex at $\lambda = 366\text{ nm}$ results in selective

SCHEME 7.9 Catalytic, enantioselective intramolecular [2 + 2]-photocycloaddition of quinolone **36** to afford cycloadducts **37** and **38** in 94% ee.

SCHEME 7.10 Proposed catalytic cycle for the enantioselective [2 + 2]-photocycloaddition of quinolone **36** in the presence of chiral catalyst **32**.

excitation of the xanthone chromophore followed by rapid triplet energy transfer from the xanthone to the bound substrate. The excited substrate then undergoes an intramolecular [2 + 2]-cycloaddition, the steric bulk of the xanthone moiety now serving to ensure that cycloaddition only occurs at one face of the bound substrate. The product is, therefore, generated as a single enantiomer and its release from the complex regenerates the catalyst to restart the catalytic cycle.

Template **33** (Scheme 7.7), which also possesses a sensitizing benzophenone moiety, was found to induce asymmetry in substoichiometric amounts in the [2 + 2]-photocycloaddition of quinolone **36**.²³ Irradiation of compound **36** in the presence of 25 mol% of catalyst **33** afforded the enantiomer of **37**, *ent*-**37**, in 19% *ee*. Increasing the catalyst loading did not significantly increase the product *ee* indicating that the low enantioselectivity was not a result of direct excitation of unbound substrate but rather that the face differentiation of the prochiral substrate by the catalyst was not sufficient.

7.3 Asymmetric Induction by Supramolecular Hosts

The distinction between Sections 7.2 and 7.3 may seem a bit arbitrary, but it is justified by the fact that the binding interactions in supramolecular hosts are frequently stronger than in low-molecular-weight templates; however, the orientation of binding is somewhat more difficult to alter and to control. Recent progress includes three major areas: cyclodextrins (Section 7.3.1), self-assembled cavitands (Section 7.3.2), and biological templates (Section 7.3.3).

7.3.1 Cyclodextrins

Cyclodextrins (CDs) are particularly attractive as host molecules because they accept a wide variety of guests with low specificity, are chiral, readily available, and easily modified. Furthermore, their transparency in the UV-vis region means they can be used in photochemical reactions. Nakamura and Inoue observed significant asymmetric induction in the cyclodimerization of 2-anthracenecarboxylate (**6**, R = CO₂[−], Scheme 7.2) in the presence of γ -cyclodextrin.²⁴ Irradiation of an aqueous solution of anthracene **6** and γ -CD (5 equivalents) at 0°C afforded the *syn*-head-to-tail (*syn*-HT) dimer “+”-**8** in 41% *ee* as the major product (46% yield). γ -Cyclodextrin can accommodate two molecules of compound **6** into its chiral cavity. The relative orientation of these molecules in the ground state complex determines the distribution and selectivity in photoproduct formation. Of the four possible isomers the HT dimers were favored due to electrostatic repulsion of the carboxylate groups (combined yields of dimers **8** and **10** were 85%–90%). In the case of chiral dimer **8** the chirality of the cavity results in one precursor complex being more stable than the other thus one enantiomer is formed preferentially.

Methyl 3-methoxy-2-naphthoate (**39**) was also found to undergo enantioselective photodimerization in the presence of γ -CD. In contrast to the previous reaction, the absence of charged groups resulted in the guest molecules favoring a head-to-head (HH) orientation in the complex. The *anti*-HH cubane-like photodimer **41** was obtained as the major product in 85% yield and 48% *ee* (Scheme 7.11).^{25,26} Isolation of the intermediate [4 + 4]-dimer **40** in 39% *ee* revealed that the chirality of cyclobutane **41** is achieved in a stepwise fashion, via an *in situ* increase of the enantioselectivity during the second step of the reaction.

While these results are promising, the inherent chirality of unmodified cyclodextrins has, in most photoreactions, been found to be insufficient to provide significant asymmetric induction.^{27,28} A greater

SCHEME 7.11 Stepwise increase in enantioselectivity during the formation of cyclobutane **41** from compound **39** in the presence of γ -cyclodextrin.

SCHEME 7.12 Structures of modified cyclodextrins 42–45.

level of success has been achieved using chemically modified cyclodextrins, several examples of which are depicted in Scheme 7.12 (42–45). Each has been rationally designed and represents a particular strategy for achieving an enantiodifferentiating photochemical reaction. Although modifications to the inside of CD have also been reported,²⁹ CDs 42–45 have all been functionalized at the 6-hydroxy position, which corresponds to the narrow rim of the CD framework.

CDs 42 and 43 have been used to produce enhanced enantioselectivity in the [4 + 4]-photodimerization of anthracenecarboxylate (6, R = CO₂[−], Scheme 7.2) by controlling the orientation of the guest molecules in the CD cavity. CDs possessing amino side arms, such as CD 42, were found to both enhance the enantiomeric excess and induce a dramatic switching in the product selectivity.^{30–32}

In the presence of unmodified γ -cyclodextrin, the HH approach is electrostatically unfavored, affording HH dimers 7 and 9 as the minor products and chiral compound “−”-7 in low *ee* (<5% *ee*). In the presence of modified CD 42 dimers 7 and 9 become the major products, obtained in a combined yield of 74%, and the enantiomeric excess of compound “−”-7 is dramatically increased to 41% *ee*. This switch in selectivity is the result of stabilization of HH complex by electrostatic interactions. At pH < 5, the diamino cyclodextrins are dicationic and form interactions with the carboxylate anions of the guest molecules.

Enantiodifferentiating catalysis has also been achieved using diamino-CDs similar to CD 42.³² Chelation of copper(II) by the side arm resulted in enhanced complexation of compound 6 (R = CO₂[−]) in the CD cavity. This not only improved the selectivity of the reaction but also made it possible to use catalytic amounts without significantly decreasing the yield or *ee*. Using only 0.1 equivalents of the metallo-CD, the *anti*-HH dimer “−”-7 was obtained in 51%–52% yield and 64%–70% *ee*.

Inoue and coworkers synthesized a series of “capped” cyclodextrins, for example, CD 43, which also demonstrated an ability to influence the orientation of the anthracene 6 in the host–guest complex.^{33,34} Modification with either a flexible or a rigid aromatic cap increased the yields of the HH dimers 7 and 9 (33%–41%), relative to native γ -cyclodextrin. This is attributed to compound 6 favoring an orientation in which the anionic carboxylate moieties are directed toward the aqueous environment and away from the hydrophobic cap. More interestingly, CD-43 was found to produce the opposite enantiomer of the chiral HT dimer, “−”-8, relative to both native CD and other capped CDs, and with enhanced enantioselectivity (58% *ee*). The authors proposed that this effect was due to much reduced positional and rotational freedom in the precursor guest–host complex, where one of the carboxylate moieties of compound 6 must protrude through the narrow gap of the biphenyl cap.

Kaliappan and Ramamurthy have used chirally modified CDs, such as CD 44, to induce low levels of enantioselectivity in photocyclizations of prochiral substrates.³⁵ For example, irradiation of adamantane 46 in the presence of CD 44 afforded photoproducts 47 and 48 in enantioselectivities of 20% and 9% *ee*, respectively (Scheme 7.13). It was anticipated that the CD cavity would serve to bring the appended chiral substituent and the achiral reactant closer together and thus achieve asymmetric induction. However, although several different enantiomerically pure amines, amino alcohols and amino acids were investigated as chiral attachments the *ee* could not be improved above 20%.

SCHEME 7.13 Irradiation of adamantane **46** in the presence of modified cyclodextrin **44** generates enantio-enriched photoproducts **47** and **48**.

SCHEME 7.14 Photoisomerization of achiral (*Z*)-cyclooctene **49** to chiral (*E*)-cyclooctenes **50**.

CD **45** is an example of a sensitizing cyclodextrin host. It possesses a tethered *m*-methoxybenzoyl group, which sensitizes the photoisomerization of (*Z*)-cyclooctene (**49**) within the cavity of the cyclodextrin affording (*E*)-cyclooctene (*R*)-(-)-**50** in 46% *ee* (Scheme 7.14).^{36,37} Both the conversion and the enantioselectivity were found to be sensitive to variations in the structure of the sensitizer moiety. The nature and position of the aryl substituent proved critical; while *meta*-methoxy substitution resulted in good asymmetric induction, the corresponding *ortho*- or *para*-substituted CDs afforded only 4%–10% *ee*. Furthermore, exchange of the methoxy group for a proton, methyl or methyl ester substituent also resulted in a dramatic decrease in enantioselectivity (1%–18% *ee*). This indicates that the chromophore not only acts as a sensitizer but also influences the enantiodifferentiation within the cavity by adjusting the position and orientation of the included guest molecule via steric effects.

Permethylation of the cyclodextrin framework was found to have an effect on the enantioselectivity of the reaction.³⁷ While this modification proved detrimental to the enantioselectivity, it resulted in inversion of the chirality of the product in response to different reaction conditions. This increased sensitivity to environmental variations is attributed to the greater flexibility of the permethylated CD due to the decrease in intramolecular hydrogen bonding.

Cyanonaphthalene-substituted CD was employed as a sensitizing host for the enantiodifferentiating photoaddition of methanol to 1,1-diphenylpropene, affording the methoxy adduct in up to 13% *ee*.³⁸ In order to enhance complex formation, the reaction was run in aqueous methanol, thus competitive photoaddition of water also occurred to afford the chiral hydroxy adduct, as the minor product, in up to 26% *ee*. In contrast to the other examples covered in this section, in this bimolecular reaction only one of the reagents, diphenylpropene, is included in the cyclodextrin cavity. Irradiation of the host–guest complex generates radical cationic diphenylpropene, via PET to the excited sensitizer moiety of the CD, and subsequent nucleophilic attack by a solvent molecule affords the anti-Markovnikov addition products. The superior enantioselectivity observed for the water adduct suggests that both the complexation and the photoaddition steps contribute to the enantiodifferentiation.

7.3.2 Self-Assembled Supramolecular Hosts

Progress in the area of asymmetric photochemistry in supramolecular hosts has largely been limited by the difficulties associated with the synthesis of novel, chiral supramolecular structures. This limitation can be overcome using self-assembled supramolecular cages or capsules. Fujita and coworkers have demonstrated that fluoranthene (**51**) and maleimide (**52**) undergo enantioselective [2 + 2]-cycloaddition in a chiral self-assembled cage, consisting of six Pd(II) fragments (M) and four pyridine-based bridging ligands (L), to afford cycloadduct **53** in 50% *ee* (Scheme 7.15).³⁹

SCHEME 7.15 Enantioselective [2 + 2]-photocycloaddition of fluoranthene (**51**) and maleimide (**52**) in a self-assembled supramolecular host.

Due to the space restriction inside the cavity, the two olefins are incorporated in a pairwise selective manner and in a precise orientation. Therefore, provided the ternary-complex is formed prior to irradiation, no homodimerization is observed, and the reaction occurs in a completely regioselective manner, affording cross-dimer **53** as the sole reaction product (55% yield). The cage also provides a considerable activation effect, allowing the use of otherwise unreactive olefins such as fluoranthene (**51**), which is an inert aromatic compound.

The chiral nature of the cavity is due to the palladium diamine end caps (M). The chirality of the diamino ligand is transferred to palladium, which results in a tilt of the pyridine rings of the coordinated triazine ligands. The magnitude of this tilt, and therefore the level of enantioselectivity, was found to be sensitive to the size of the *N*-substituent. When the ethyl group was replaced with a methyl substituent or a proton, the enantioselectivity decreased to 20% *ee* and 5% *ee*, respectively.

7.3.3 Biological Templates

The chiral environment of biomolecules can be exploited to induce asymmetry in photochemical reactions. Natural supramolecular hosts that have been investigated to date include DNA,^{40,41} RNA⁴¹ and proteins, namely, bovine^{42,43} and human^{44,45} serum albumin. The pioneering work in this area was achieved using RNA and DNA. Inoue and coworkers demonstrated that these molecules act as chiral sensitizing hosts for the photoisomerization of cyclooctene (Scheme 7.14). Irradiation of an aqueous solution of (*Z*)-cyclooctene (**49**) in the presence of calf thymus DNA afforded the (–)-(*E*)-isomer, (*R*)-(–)-**50**, in *ees* of up to 15%.

The best results have, however, been obtained using the serum albumins. These blood carrier proteins possess several binding pockets, within which enantioselective photochemical reactions can take place. Inoue and coworkers have investigated the [4 + 4]-photocycloaddition of anthracenecarboxylate (**6**, Scheme 7.2) in the presence of both bovine (BSA) and human serum albumin (HSA).

In the presence of BSA, the photodimerization of anthracene **6** takes place enantioselectively to afford chiral products “+”-**7** and “–”-**8** in *ees* of up to 41% and 29%, respectively.⁴² The regioselectivity of the reaction is switched such that the HH products (**7** and **9**) become favored over the HT products (**8** and **10**) in ratios of up to 4.3:1. The reaction is highly sensitive to the concentration of BSA relative to compound **6**. Not only is the rate of photodimerization reduced by high BSA concentrations but the HH/HT ratio and *ees* of compounds **7** and **8** are also a function of the BSA concentration. The relationship between concentration and *ee* is complex and the authors propose that this may be due to different binding sites inducing different enantioselectivity. BSA possesses four independent sites at which anthracenecarboxylate can bind. Studies indicated that each site is distinctly different in regard to the chiral environment it provides, the number of molecules it can bind (between one and three), and the binding affinity.⁴³ As opposed to the

SCHEME 7.17 Enantioselective photocyclization of diphenylpentenol **56** to tetrahydrofuran **57**, sensitized by arene **55a**.

(alcohol), solvent, and temperature on the yield and *ee* of photoadduct.⁵¹ In terms of enantioselectivity, the best results were achieved using diisopropylidene-fructosyl (**a**, Scheme 7.16) substituted 2,6-naphthalene dicarboxylate as the sensitizer, in combination with a bulky nucleophile (2-propanol). The highest *ee* was obtained when the reaction was carried out at 0°C in diethyl ether, affording the addition product in 58% *ee*, albeit in only 1% yield. While better yields could be obtained using smaller nucleophiles or different solvents, this was accompanied by a decrease in enantioselectivity. Studies conducted in near- and supercritical CO₂ (sc-CO₂) showed that product *ee* increases with increasing pressure.^{52,53} This increase was particularly pronounced in the narrow pressure range near the critical density.

In the analogous intramolecular reaction, the enantiodifferentiating photocyclization of 5,5-diphenyl-4-penten-1-ol (**56**) was sensitized by diisopropylidene-fructosyl 1,4-naphthalenedicarboxylate (**55a**) to afford tetrahydrofuran **57** as the major product (Scheme 7.17).⁵⁴ Enantioselectivities of up to 28% were obtained in low-polarity solvents such as methylcyclohexane, toluene, or diethyl ether. When this reaction was carried out in supercritical CO₂, the *ees* were comparable to those obtained in conventional solvents; however, the addition of diethyl ether as a cosolvent (entrainer) was found to significantly enhance the enantioselectivity affording compound **57** in up to 45% *ee*. Diethyl ether had previously been shown to improve the enantioselectivity of similar reactions by enhancing the microenvironmental polarity around the sensitizer, thus facilitating electron transfer within the exciplex intermediate.^{48,51}

7.5 Asymmetric Induction by Conformational Constraints

The first stereogenic center in a molecule can be created from precursors that carry another element of chirality, that is, a chiral axis or chiral plane, without the need for any external chiral source. While this other element of chirality may not be infinitesimally stable, it may still be sufficient to transport chiral information. Along these lines, some recent developments are summarized in this section. Particular emphasis is given to axial to point chirality transfer (Section 7.5.1) and chiral memory effects (Section 7.5.2).

7.5.1 Axial to Point Chirality Transfer

Carreira and coworkers have exploited the axial chirality of allenes to achieve asymmetric induction in intramolecular [2 + 2]-cycloaddition reactions (Scheme 7.18).^{55,56} Enantiomerically pure 1,3-disubstituted allenes, such as **58**, readily undergo allene-enone photocycloaddition reactions, affording the corresponding cycloadducts (**59**) in between 76% and 99% *ee*.

Stereochemical control is derived exclusively from the axial chirality of the allene moiety, which possesses either a tertiary butyl- or trimethylsilyl group. The absolute configuration is established in the initial C–C bond-forming step, with addition of the excited enone to the allene occurring at the face opposite the bulky silyl substituent. Although the allene starting material is optically active the reactions are considered enantioselective as the stereogenic centers in the product are generated at the expense of the axial chirality of the allene. The trimethylsilyl derivatives were developed in order

SCHEME 7.18 Intramolecular [2 + 2]-photocycloaddition of allene **58** to generate chiral cyclobutane **59** in 99% ee.

to increase the synthetic versatility of this reaction. Following the photocycloaddition, cleavage of the stereocontrolling group from the chiral product can be carried out with TBAF to afford the unsubstituted *exo*-methylene compound **60**.⁵⁶

Atropisomers are axially chiral molecules that arise from restricted rotation around single bonds, as opposed to the multiple bonds of allenes. In molecules of this type, the barrier to rotation is large enough to allow the isolation and characterization of the individual rotamers. Earlier work has revealed that atropisomerism can be used to induce facial diastereoselectivity in a Paternò-Büchi reaction.⁵⁷ Recently, it was demonstrated that atropisomeric starting materials undergo enantioselective photochemical reactions in solution by an effective and almost complete axial to point chirality transfer.^{58,59} Acrylanilide **61** exists as individual atropisomers (designated *P* and *M*) due to restricted bond rotation around the N–C(aryl) bond (Scheme 7.19). Irradiation of optically pure (+)-**61** resulted in [6 π]-photocyclization to afford a mixture of the *cis*-photoproduct **62** and the *trans*-photoproduct **63**, in 99% ee. The identical enantiomeric excesses of the diastereomeric products indicate that the stereogenic center at the benzylic position is formed first, in a highly stereoselective ring closure step, while the second stereogenic center is generated with loss of the *ortho* *t*-butyl substituent in a nonselective proton-transfer step. Irradiation of the optical antipode, (–)-**61**, afforded the opposite enantiomers, *ent*-**62** and *ent*-**63**.

In a subsequent paper, Sivaguru et al. reported that atropisomeric α -oxoamides also undergo enantioselective photocyclization, via a Norrish–Yang mechanism involving axial to point chirality transfer, to afford β -lactam products in 72%–80% ee.⁵⁹

For systems that do not exist as separable atropisomers chiral crystallization can be used to generate axial chirality. If a prochiral substrate crystallizes in a chiral space group, enantiomerically pure crystals are generated. If that molecular chirality is maintained even after the crystals are dissolved in a solvent, it can be transferred during a reaction to afford enantiomerically pure products. Sakamoto and coworkers have demonstrated that asymmetric photochemical reactions are possible by exploiting this “frozen chirality.”^{60,61} *N,N*-Diethyl-4-coumarin-3-carboxamide has two possible conformations, (*R*)-**64** or (*S*)-**64** (Scheme 7.20). When in solution this molecule is considered prochiral due to rapid interconversion *via* bond rotation. However, compound **64** crystallizes in a chiral space group to afford enantiomerically pure crystals composed of either the (*S*)- or (*R*)-enantiomer. When singularly chiral crystals were dissolved in methanol at –20°C, the molecules retained their chirality and effectively underwent triplet-sensitized intramolecular [2 + 2]-photocycloaddition with alkenes to generate cyclobutane products, for example, **65**, in high enantioselectivity (97%–99% ee). The use of benzophenone as a triplet sensitizer was found to be essential as in the singlet-state photoracemization occurs, affording racemic products.

SCHEME 7.19 6 π -Photocyclization of molecularly chiral acrylamide **61** to afford chiral photoproducts **62** and **63**.

SCHEME 7.20 Generation of singularly chiral crystals of compound **64** by chiral crystallization and [2 + 2]-photo-cycloaddition of isomer (R)-**64** to afford cyclobutane **65** in 99% ee.

7.5.2 Chiral Memory Effect⁶²

The first example of a chiral memory effect in photochemistry was reported by Giese and coworkers.⁶³ The Norrish–Yang photocyclization of alanine derivative **66** was shown to occur without racemization, despite proceeding *via* a prochiral diradical intermediate, to afford proline derivative **68**, as the major product, in 40% yield and 92% ee (Scheme 7.21). The corresponding *trans*-isomer was obtained as the minor product (7% yield, 88% ee). The asymmetric induction was drastically reduced in the absence of a triplet quencher (naphthalene), leading the authors to propose that the lifetime of the triplet diradical is long enough to allow racemization to occur. In contrast, in the singlet state, the activation barrier to cyclization is lower than that of bond rotation, resulting in almost complete memory of chirality. Calculations were later performed, which indicated that a hydrogen bond network in the helical intermediate **67**, involving the N-6, H-9, and O-12 atoms, is the likely reason for this barrier to rotation.⁶⁴

In contrast to the previous example, where formation of a triplet diradical results in almost complete loss of chirality, Griesbeck and coworkers observed high enantiomeric excesses for decarboxylative

SCHEME 7.21 Norrish–Yang photocyclization of chiral alanine derivative **66** to compound **68** occurs without racemization despite proceeding through prochiral diradical **67**.

SCHEME 7.22 Decarboxylative photocyclization of proline derivative **69** proceeds via an atropisomeric 1,7-diradical to generate compound **70** in 86% ee.

photocyclization reactions involving a triplet 1,7-diradical. Irradiation of proline derivative **69** afforded the pentacyclic product **70** in 86% *ee* with a diastereoselectivity of greater than 98% (Scheme 7.22).⁶⁵ In this case, the 1,7-diradical is atropisomeric, with a calculated barrier to rotation of 55 kJ mol⁻¹, resulting in preserved axial chirality that is transferred to the stereogenic centers in the product.

Enantiomerically pure thioimides have been shown to undergo photochemical intramolecular β - or γ -hydrogen abstraction reactions involving a chiral memory effect to afford optically active products. Sakamoto and coworkers generated new stereogenic quaternary carbon centers from the tertiary chiral centers of readily accessible amines and amino acids with almost complete retention of stereochemistry (96%–100% *ee*).⁶⁶ This approach was also applied to the synthesis of chiral β -lactams.⁶⁷ Irradiation of thioimide **71** afforded a mixture of β -lactams **72** and **73** in 96% and 95% *ee*, respectively (Scheme 7.23). Intramolecular β -hydrogen abstraction by the aryl thiocarbonyl group from the stereogenic center of substrate **71** generates a singlet 1,4-diradical intermediate. Subsequent radical recombination occurs faster than racemization, *via* bond rotation around the radical site, so the products are generated in high enantiomeric excess.

Double memory of chirality (²MOC), in which *two* stereogenic centers retain their chiral information, is known to be possible in the solid state since the reacting centers are held in close proximity and large molecular motions, such as radical rotation, are energetically disfavored. Garcia-Garibay et al. have now proven that ²MOC is also possible in solution (Scheme 7.24).⁶⁸ Irradiation of *bis*-(*N*-methylphenylpyrrolidinonyl)-ketone (**74**) in benzene at 25°C resulted in photodecarbonylation with double memory of chirality affording compound **77** possessing two adjacent stereocenters. The reaction occurs *via* the singlet state (**75** \rightarrow **76**) on a picosecond timescale, thus providing insufficient time for the two radical fragments to rotate and expose the other enantiotopic face before radical recombination takes place.

SCHEME 7.23 Enantioselective generation of two new stereogenic quaternary centres in the cyclization of thioimide **71** to β -lactams **72** and **73**.

SCHEME 7.24 Double memory of chirality in the photodecarbonylation of ketone **74** to compound **77**.

SCHEME 7.25 1,2-Chirality transfer in the cyclization of compound (R)-78 to cyclopropane (R)-80, via transition state 79.

One final example of chiral memory is point-to-point chirality transfer, in which one transition state geometry is favored, resulting in transfer of the chiral information from the starting material to the product. Cyclopropane derivatives (e.g., 80) were generated from chiral phenylalkyl ketones (e.g., 78) in up to 83% ee, via a modified Norrish–Yang cyclization involving a 1,2-chirality transfer (Scheme 7.25).⁶⁹ Compounds of type 78 adopt a six-membered, chair-like conformation in which the leaving group (X) is either pseudoaxial (79) or pseudoequatorial (79'). In each transition state, hydrogen transfer can only occur from one of the two diastereotopic methylene groups (*), generating a stereogenic center at the β -position. Subsequent loss of the leaving group generates a 1,3-diradical, which cyclizes to afford the chiral cyclopropane product (80). A combination of enthalpic and entropic factors determines which transition state is favored, so the absolute configuration of the major product is not the same for all substrates, despite all the starting materials possessing the (*R*)-configuration.

7.6 Asymmetric Aminocatalysis

Very recently, it has been demonstrated that chiral amine catalysts can be used in conjunction with photochemical processes to achieve new enantioselective reactions.

Córdova et al. performed asymmetric α -oxidations using aminocatalysis and photochemically generated singlet oxygen (Scheme 7.26).⁷⁰ They demonstrated that amino acids catalyze the reaction of aldehydes (e.g., 81) with singlet molecular oxygen to afford a chiral α -hydroperoxide species (e.g., 83), which can be reduced *in situ* to the corresponding diol (e.g., 84). L- α -Methyl proline (82) was the amino acid found to provide the most effective asymmetric induction, affording the diol products in enantiomeric excesses of between 54% and 66% ee.

The reaction is presumed to proceed *via* an enamine pathway. Condensation of the aldehyde with catalyst 82 both activates the aldehyde to electrophilic attack and results in face differentiation of the prochiral starting material due to the directing effects of the proline carboxylic acid group. Singlet oxygen reacts with the resultant enamine *via* an ene-type reaction to generate an iminium ion, which is in equilibrium with aldehyde 83 and thus regenerates the catalyst.

SCHEME 7.26 Enantioselective ene-type reaction of $^1\text{O}_2$ and aldehyde 81, catalyzed by α -methylproline (82).

SCHEME 7.27 Structures of the catalysts **85**–**87** used in photoredox organocatalysis.

Nicewicz and MacMillan have successfully merged the areas of aminocatalysis and photoredox catalysis to achieve an enantioselective α -alkylation of carbonyl compounds.^{71,72} The reaction involves the cooperation of two independent catalytic cycles and thus requires a dual catalyst system (Scheme 7.27) consisting of an enantiomerically pure secondary amine (e.g., **85**) and a photoredox catalyst (e.g., **86** or **87**).

Enantioselectivity and activation of the substrate is once again achieved *via* an enamine pathway (Scheme 7.28). *In situ* condensation of aldehyde **88** and imidazolidinone catalyst **85** generates an electron-rich enamine intermediate **89**, which undergoes addition of an electrophilic radical ($\cdot Y$). Due to the face differentiation provided by the chiral amine catalyst, this addition occurs stereoselectively generating radical intermediate **90** as a single enantiomer. Here, the two catalytic cycles converge. Intermediate **90** is oxidized by single electron transfer (SET) to the excited photoredox catalyst ($^*Ru^{2+}$) to afford the corresponding iminium ion **91**, which then undergoes hydrolysis to yield the final product **92** and regenerates the amine catalyst.

Concurrent with the enamine pathway given earlier, a photoredox catalytic cycle takes place involving $[Ru(bpy)_3]^{2+}$ (**86**) a well-established one electron photoredox catalyst. Irradiation of $[Ru(bpy)_3]^{2+}$ results in metal-to-ligand charge transfer, generating the excited-state $^*[Ru(bpy)_3]^{2+}$, which possesses enhanced reactivity relative to the ground-state molecule. $^*[Ru(bpy)_3]^{2+}$ then acts as an oxidant, removing one electron (SET) from the α -amino radical **90**, generating $[Ru(bpy)_3]^+$, which is a powerful reducing agent. A second SET process involving the starting halide ($X-Y$) and $[Ru(bpy)_3]^+$ generates the electron-deficient radical ($\cdot Y$) required for the alkylation step and regenerates the photoredox catalyst **86**.

SCHEME 7.28 The enantioselective α -alkylation of carbonyl compounds (e.g., **88**) involves two independent catalytic cycles to generate products **92** in excellent *ee*'s.

Considering that a complex interplay of two independent catalytic processes is required for this reaction to succeed, the yields (63%–93%) and enantiomeric excesses (88%–99% *ee*) achieved are remarkable. The reaction is also operationally simple, no heating or cooling is required, and a 15 W fluorescent light is used as the light source. 20 mol% of the amine catalyst is used while only 0.5 mol% of the photoredox catalyst is required. More recently, MacMillan and coworkers reported that α -fluoroalkylation of aldehydes is also possible using this methodology.⁷² α -Trifluoromethyl and α -perfluoroalkyl derivatives of a variety of aldehydes were prepared in yields ranging from 62% to 89% and in 96%–99% *ee*. In this case, the iridium-based catalyst **87** (Scheme 7.27) proved superior and the reaction required cooling to -20°C in order to achieve an asymmetric induction.

8.1 Introduction

Ring closure reactions are of fundamental importance in organic chemistry due to the broad occurrence of cyclic structural elements both in natural products and in synthetic drugs. Besides many valuable thermal methods, photochemical ring closure reactions gained increasing importance in recent years. Among the various photochemical cyclization reactions, the *Norrish–Yang* reaction [1] turned out to be particularly versatile.

In 1934, *Norrish* and *Appleyard* observed upon irradiation of aliphatic ketones **1** ($R^1 = \text{alkyl}$, $X = C[sp^3]$) a cleavage reaction providing ketones **3**, whose alkyl chain was cleaved between the α - and the β -carbon atom with respect to the carbonyl group, and alkenes **4** [2]. Nowadays, this cleavage reaction is named “*Norrish-Type-II* cleavage.” Certainly due to the limited analytical capabilities 75 years ago, it was only *Yang* and *Yang* who recognized 23 years later the formation of cyclobutanes **5** besides the *Norrish-Type-II* cleavage products (**3,4**) [3]. This discovery was the basis of a very versatile and valuable ring closure reaction that has therefore been termed “*Norrish–Yang* reaction.” Diradicals **5** (in singlet or triplet state) are key intermediates of this reaction and play a central role in the mechanism of the *spin-center shift* reactions discussed in this chapter (Scheme 8.1).

Depending on the linking group X in the reactants **1**, a variety of carbo- and heterocyclic compounds has been prepared by means of the *Norrish–Yang* reaction. Accordingly, cyclopropanes, cyclobutanes (the *Yang* reaction in the narrow sense), azetidines, oxetanes, cyclopentanes, pyrrolidines, tetrahydrofuranes, cyclohexanes, piperidines, quinolines, chromanes, and some macrocyclic compounds were obtained in this way [4]. On one hand, the variety of different cyclic molecules obtained by the *Norrish–Yang* reaction demonstrates the synthetic scope of this reaction. On the other hand, the ring size formed from a certain reactant can hardly be influenced. The basic idea of the *spin-center shift* reactions (in the narrow sense, *vide infra*) is to combine the *Norrish–Yang* reaction with fast processes known from monoradicals, which are accompanied with a shift of the spin center, and, consequently, alter the ring size of the products.

The reactions of radicals could be roughly subdivided into those destroying the radical character and those preserving it. The two most important radical-destroying reactions are the radical recombination

SCHEME 8.1 Norrish–Yang reaction and Norrish-Type-II cleavage.

SCHEME 8.2 The spin-center shift in the narrow sense.

and the radical disproportionation. Reactions preserving the radical character are rearrangement reactions, addition reactions, and elimination reactions. All of these reactions have in common that the position of the radical center is shifted to another atom in the course of the reaction. Looked at in this way, these reactions could be understood as *spin-center shift* reactions in the broader sense.

Among various types of elimination reactions of radicals, one process is based on the elimination of a leaving group (or the corresponding acid) located on the atom adjacent to the radical center. This process is strongly facilitated if a hydroxy or an alkoxy group is tethered at the radical center. Thus, radicals **6** undergo very rapid elimination either to radical cations **7** or to oxoallyl radicals **8** (sometimes called “enolate radicals”) depending on the functional group at the radical center. In both cases, the spin density is shifted to the adjacent atom (Scheme 8.2). We define photochemical reactions involving the *Norrish–Yang* reactions and the reactions summarized in Scheme 8.2 as *spin-center shift* in the narrow sense (SCS-NY) and this is the topic of this chapter [5].

It should be noted that the reactions outlined in Scheme 8.2 play also an important role in some biochemical processes, for example, the deoxygenation of ribonucleotides [6] or the damage of DNA by oxidative stress [7].

8.2 Cyclopropanes

8.2.1 Monocyclic Cyclopropanes

The precondition for the synthesis of cyclopropanes as products of a *Norrish–Yang* reaction is the formation of 1,3-diradicals and consequently a hydrogen abstraction from the β -position with respect to the carbonyl group. The geometrical parameters of the corresponding five-membered transition state, especially the O–H–C bond angle, differ substantially from the ideal parameters reported by Scheffer [8]. Therefore, it is not surprising that only few syntheses of cyclopropanes via the *Norrish–Yang* reaction are known [9–11].

This situation was substantially improved by the utilization of the SCS for the synthesis of cyclopropanes [12]. The reactants for the cyclopropane synthesis by SCS-NY are alkyl-aryl ketones **9** bearing a leaving group X at the atom adjacent to the carbonyl carbon atom. Upon irradiation, hydrogen migration from the γ -position to the carbonyl oxygen atom takes place after intersystem crossing (ISC), giving the 1,4-diradical **10**. If the leaving tendency of X is too low (e.g., X = OC(=O)R, Cl), mainly the products of the *Norrish–Yang* reaction and *Norrish-Type-II* cleavage are formed from **10** [13], whereas for X = Br a homolytic C–Br bond cleavage is observed [13b]. In the case of good leaving groups, such as sulfonates and nitrates, a very rapid elimination of acid HX takes place and 1,3-diradicals **11** are obtained, which cyclize to cyclopropanes **12** after repeated ISC to the singlet state (Scheme 8.3).

SCHEME 8.3 Formation of cyclopropanes **12** by NY-SCS.TABLE 8.1 Yields of Cyclopropanes **12a–e**

d	H	CN	OMs	65
e	H	<i>c</i> Pr	OTs	68

Conditions: DCM/NMI (2 equivalents).

A common feature of all preparative SCS applications is the formation of strong acids HX during the irradiation. In the presence of these acids, benzoylcyclopropanes **12** are not stable upon irradiation but undergo rapid ring opening. Consequently, an efficient acid scavenger must be added and it was found that imidazole or *N*-methylimidazole (NMI) is best suited for this purpose. The reaction outlined in Scheme 8.3 is very versatile and tolerates many functional groups. The yields of a selection of cyclopropanes **12** are summarized in Table 8.1.

The formation of compound **12e**, bearing a cyclopropyl group, allows conclusions to be drawn about the lifetimes of diradicals **10** and **11**. It is well known that those cyclopropylcarbinyl radicals undergo a very fast ring opening ($k = 4.0 \times 10^7 \text{ s}^{-1}$) and this reaction was often utilized for the determination of radical lifetimes [14]. Consequently, the formation of dicyclopropylketone **12e** in 68% yield and without any indication of an opening of the terminal cyclopropyl ring proves that the sum of the lifetimes of the primarily formed 1,4-diradical **10** and 1,3-diradical **11** is considerably smaller than 25 ns.

8.2.2 Bicyclic Cyclopropanes: 1,2-Chirality Transfer

Extensive quantum chemical calculations on the cyclopropane formation [12b] revealed an interesting peculiarity in the reaction mechanism. Thus, owing to hyperconjugative interaction between the C–X– σ -bond and the semi-filled π -orbital of the excited carbonyl group, the transition states of the initial hydrogen transfer (**9** \rightarrow **10**) prefer a conformation **TS¹** in which the leaving group is arranged pseudoaxially in the cyclohexane-like ring. This phenomenon led to the development of an entirely new stereoselection principle based on a 1,2-chirality transfer [15]. The principle of this approach is portrayed in Scheme 8.4 in simplified terms. If two identical groups R–CH₂ are tethered at the β -position, this atom may be regarded as prochirality center and the positions γ^1 and γ^2 are diastereotopic. On the

SCHEME 8.4 Principle of the 1,2-chirality transfer in the course of the SCS-NY cyclopropane synthesis.

basis of the preference of TS^1 , the excited carbonyl group should preferably attack the position γ^2 . In the course of the SCS, the chirality center in α -position vanishes, and the chiral information is transferred to the β -carbon atom (1,2-chirality transfer, Scheme 8.4).

This principle was applied to a series of enantiopure ketones **R-13**, which have in common that the groups *R* (see Scheme 8.4) are parts of a saturated six-membered ring (Scheme 8.5). The photochemical behavior of these ketones in different solvents and at different temperatures was investigated and the results are summarized in Table 8.2.

SCHEME 8.5 Photochemical cyclization of ketones **R-13**.

^c The *t*Bu substituent is *trans* arranged with respect to C- β .

^d A doubtless assignment with VCD spectroscopy was not possible.

The formation of bicyclic ketones **14** proceeds with a significant chirality transfer, in most cases, which depends on the solvent. To verify the postulated stereochemical course depicted in Scheme 8.5, it was necessary to determine the absolute configuration of the preferably formed enantiomer of compounds **14a–d**, which succeeded in most cases by application of vibrational circular dichroism (VCD). By this method, which is based on the comparison of experimental and calculated VCD spectra, it was possible to unambiguously determine the absolute configuration of **14a–d**.

As lowering of the reaction temperature often leads to an increase in stereoselectivity, the temperature dependency of stereoselectivity of the photocyclization of compounds *R*-**13** was investigated. Exemplarily, in Figure 8.1, the relevant Eyring plots for **14b** ($\ln([R\text{-}14b]/[S\text{-}14b]) = f(1/T)$) are shown for irradiation in the solvents dichloromethane (DCM) and methanol (MeOH). Surprisingly, in both solvents, an increasing stereoselectivity with increasing temperature starting from r.t. was found, a behavior, which was previously observed in other photochemical reactions. Photochemically induced reactions with a selectivity reversal at T_0 [$\ln(A/B) = 0$] [16]. The phenomenon appears if the differences of enthalpies of activation $\Delta\Delta H^\ddagger$ and entropies of activation $\Delta\Delta S^\ddagger$ for the formation of both enantiomers have the same sign. According to Equation 8.1, the selectivity *Se* can be calculated from the difference of free activation energies $\Delta\Delta G^\ddagger$, which can be subdivided in an enthalpy and an entropy term. At a certain temperature T_0 , expressed by Equation 8.2, these terms may compensate each other and any selectivity vanishes. Upon crossing the temperature T_0 , the sign of the selectivity is reversed. The activation parameters $\Delta\Delta H^\ddagger$ and $\Delta\Delta S^\ddagger$ as well as T_0 , obtained from the slopes of the lines in Figure 8.1, are summarized in Table 8.3.

$$Se = \ln\left(\frac{k_A}{k_B}\right) = \frac{-\Delta\Delta G^\ddagger}{RT} = -\frac{\Delta\Delta H^\ddagger}{RT} + \frac{\Delta\Delta S^\ddagger}{R} \quad (8.1)$$

$$T_0 = \frac{\Delta\Delta H^\ddagger}{\Delta\Delta S^\ddagger} \quad (8.2)$$

8.2.3 Spiro[2.2]pentanes

From investigations on the *Norrish–Yang* reaction, it is well known that the initial intramolecular hydrogen abstraction preferentially takes place at the γ -position of the alkyl side chain [1]. The most established method to prevent a γ -H-shift is to block this position (\neq C(sp³)-H). Furthermore, a *Norrish–Yang* macrocyclization is described for reactants with a cyclopropane moiety located in γ - and δ -position of the side chain [17]. In this case, the significantly higher C–H bond dissociation energy (BDE) of cyclopropane seems to be responsible for the absence of γ -H-abstraction. On the other hand, the cyclopropane formation by SCS-NY (*cf.* preceding section) is characterized by a considerable higher thermodynamic driving force compared with the “normal” *Norrish–Yang* reaction [12]. Therefore, the photochemical behavior of the *cis*-configured 2-mesyloxy cyclopropyl ketone **15** was investigated to find out whether a hydrogen abstraction from the ϵ -position takes place (Scheme 8.6) [18].

After irradiation (≥ 300 nm) of **15** in DCM, MeOH, and *t*BuOH, respectively (in the presence of two-equation NMI), no formation of the desired bicyclic ketone **16** could be observed. Instead, the phenyl ketone **17** without leaving group is generated as a consequence of an intermolecular hydrogen shift from the solvent. This is in good agreement with the photochemical behavior of 2-sulfonyloxy phenyl ketones without γ -C(sp³)-H [19]. The question arises which course the reaction will take in the absence of a potential hydrogen donor. Irradiation of **15** in perhalogenated 1,1,2-trichloro-1,2,2-trifluoroethane (R113) leads to a surprising result: the formation of spiro[2.2]pentane **18** as a 1:1 mixture of two diastereomers due to a γ -hydrogen shift.

In contrast to **15**, only one spiro[2.2]pentane isomer is possible in the case of ketone **19**. In fact, complete conversion of **19** on irradiation in R113 and in the presence of NMI (2 equivalents) gave the spiro[2.2]pentane **20** predominantly. In addition, an isomeric methylenecyclobutane **21** resulted (**20**:**21** = 82:18) (Scheme 8.7). By separate irradiation of **20**, it was found that **21** arises from **20**.

The photochemical skeletal rearrangement of **20** to **21** could be explained by a cyclopropane ring opening to 1,3-diradical **22**, which underlies a cyclopropylcarbinyl ring opening (“radical clock”) to diradical **23** [14].

SCHEME 8.6 Photochemical behavior of ketone **15**. ([a]: ≥ 300 nm, solvent: DCM, MeOH, or *t*BuOH. [b]: 1:1 mixture of 2 diastereomers. R113: 1,1,2-trichloro-1,2,2-trifluoro-ethane).

SCHEME 8.7 Photochemical behavior of ketone 19.

8.3 1-Indanones and Dihydrobenzo[c]furans

The synthesis of cyclopropanes by SCS-NY (Section 8.2) is based on reactants bearing the leaving group within the carbon chain linking the excited carbonyl group and the attacked C–H bond. If the leaving group X is positioned beyond this carbon chain, another mode of SCS is observed. Accordingly, if *o*-alkylaryl-alkyl ketones **24** are irradiated, hydrogen abstraction from the *o*-alkyl residue takes place and 1,4-diradicals **25** are formed (Scheme 8.8). These diradicals may be regarded as triplet form of *o*-quinodimethanes and their lifetimes are considerably longer than that of nonconjugated diradicals [20]. Elimination of acid HX furnishes 1,5-diradicals **26**, which cyclize, after ISC, to 1-indanones **27** [21a]. Owing to the mentioned longer lifetimes, this process tolerates weaker leaving groups X such as phosphates (**24h**) and even carbonates (**24i,j**). Therefore, this system should be suitable for novel photocleavable protective groups [22] for phosphates and alcohols. Indeed, Klán and Wirz demonstrated that 2,5-dimethylphenacylesters [23a–c,e] and carbonates [23d] are excellent protective groups for carboxylic acids, phosphates, sulfonates, alcohols, and phenols. On an application of 2-methyl-phenacylesters as photocleavable linkers in solid phase synthesis was reported as well [24]. The yields of selected 1-indanones **27** are summarized in Table 8.4.

SCHEME 8.8 Photochemical behavior of ketones 24.

m	H	CN	OMs	58	A

^a Conditions: A—MeOH/NMI (2 equivalents), B—MeOH, C—DCM/NMI, D—*t*BuOH.

Ketones **24** with an electron withdrawing group at R¹ (**24e,f**) provide 1-indanones **27** only in good yields if *t*BuOH is used as solvent (condition D) whereas in DCM dihydrobenzo[*c*]furanones **30** are formed as main products. This result could be explained by a shift of the mesomeric equilibrium of oxoallyl radical moiety from carbon centered **28** to oxygen centered **29** (Scheme 8.8, *cf.* Scheme 8.2).

The SCS-NY method for the preparation of 1-indanones was utilized in the total synthesis of pterosines, a class of cytotoxic natural products occurring in *bracken fern* [21b]. Thus, the fivefold substituted aryl ketones **31**, prepared in 13 steps from 2,6-dimethylphenol, provided upon irradiation in *tert*-butanol 1-indanones **32**. By two additional steps **32a** was converted to Pterosin B (**33**), whereas **32b** provided Pterosin C (**34**, Scheme 8.9).

Klán and coworkers reported on the photochemical synthesis of 1-indanones related to donepezil, an acetylcholinesterase inhibitor used in the treatment of Alzheimer's disease [25].

SCHEME 8.9 Total synthesis of Pterosines B and C: (a) 1. K₂CO₃/MeOH, 91%, 2. LDA (two equations)/MeI, 43%. (b) 1. PLE/HEPES, 54%. 2. Three-equation LDA (three equations)/MeI 49%.

SCHEME 8.10 Preparation of oxazinones **38**.

8.4 Oxazinones

The synthesis of cyclopropanes (Section 8.2) and 1-indanones (Section 8.3) by SCS-NY is based on the carbon-centered mesomer **8a** (see Scheme 8.2) of the oxoallyl radical moiety. In the preceding section, it was shown that this mode of reaction is altered if an electron withdrawing group is directly tethered to the oxoallyl radical moiety (formation of dihydrobenzo[c]furans **30**). This also applies to the photochemical behavior of α -methanesulfonyloxy- β -ketoamides **35**. These compounds are easily accessible by treating of β -ketoamides with hypervalent iodine-(III) reagents [26]. On irradiation, 1,5-diradicals **36** are formed, which are converted into diradicals **37** by elimination of methanesulfonic acid. In contrast to the cyclopropane and 1-indanone synthesis, the enolate radical moiety of diradicals **37** reacts solely as oxygen radicals **37a** to give oxazinones **38** (Scheme 8.10) [27].

9.1 Introduction

Nature represents the most significant source of inspiration for researchers, due to the fact that several problems (still unresolved for scientists) have been ingeniously overcome by living organisms, thanks to evolution. A well-known example is represented by plants. Starting from simple materials, such as carbon dioxide, water, and mineral salts, they are able to synthesize a wide range of complex organic molecules, with efficient (and often stereoselective) processes, under mild conditions (room temperature, physiologic pH, and aqueous media). Moreover, the only energy source required is solar light and the only side product is molecular oxygen. What chemists can do is to search inspiration from these ideal laboratories, trying to replicate the same reactions in an artificial way. Although this biomimetic approach has been adopted since early decades of 1900 (see, e.g., Ciamician's research), only in recent years it has been formulated, together with the concept of green chemistry. During the twentieth century, a series of tragic events in the chemical industry, caused partially by both safety shortage and lack of environmental awareness (e.g., Cuyahoga river's fire, Bhopal, and Seveso accidents), impacted deeply on the attitude of public opinion toward chemistry (and sciences in general). These episodes, together with the consciousness of humanity of depending almost exclusively on nonrenewable (and pollutant) energy sources, such as fossil fuels, led to a report from the United Nations World Commission on Environment and Development, published in 1987, and called "our common future" [1]. This is actually considered as the first official proposal of a sustainable development for industry and, in general, for civilization. If the

concepts “green synthesis,” “environmental benign,” and “sustainable chemistry” are nowadays familiar to chemists and the development of environmental-friendly processes (on both industrial and laboratory scale) is considered as a priority, this is due to the incisive work of few research groups. The formulation of the 12 principles of green chemistry by Anastas and Warner [2] in 1991, then the concept of “atom economy” introduced by Trost [3], and the *E*-factors proposed by Sheldon [4,5] to quantify the greenness of a chemical process give an idea of how fast the mergence of a “green conscience” in chemical sciences was.

In our opinion, a reaction must satisfy four primary conditions, in order to be considered “green”:

1. An efficient use of energetic sources
2. A minimization of hazards related both to the use of chemicals and to reaction conditions
3. Minimization of waste
4. Use of renewable resources

Summing up, an ideal eco-friendly process might take place efficiently starting from nontoxic and cheap substrates, in the absence of solvent (or, at least, in water) and without heating. As suggested by natural photosynthesis in plants, synthetic photochemistry could play a significant role in the development of ecosustainable synthetic processes. It is a matter of fact that light is a “chemical principle” (according to the definition proposed by Priestley in 1790 [6], that activates reagents, leading to the desired products without the employ of harsh conditions (high temperature or pressure) or catalysts. Practically, photons are a “safe and clean reagent,” because they leave no residues in the reaction mixture, making both workup and purification procedures easier. As mentioned earlier, the synthetically green potentialities of light were described and exalted in the early twentieth century, thanks to the pioneering contributions by Giacomo Ciamician and Emanuele Paternò [7]. Their suggestions were then revisited, a few decades later, by Schönberg [8] and Schenck [9], in their fundamental studies on the photoreactivity of carbonyls and on photo-oxidations, respectively. Notably, most of the reported reactions were carried out under conditions that only now are recognized as “green,” including solvent-free conditions or sunlight illumination [6]. In particular, immediately after the Second World War (1947), Schenck developed a pilot plant for the synthesis of antihelmitic ascaridole, based on sunlight exposure of an aerated solution of α -terpinene in a stinging nettle leaves ethanol extract [9]. Although his plant was technically limited by the critical *post bellum* situation in Germany, in our opinion it still represents for photochemistry (and chemistry in general) the way to ecosustainability, because of the use of a renewable solvent (ethanol), nontoxic reagents (e.g., air and chlorophyll, used as natural photosensitizer) and sunlight as energy source. Despite these early promising results, a wide application of photochemistry has never really started, probably due to the fact that several limitations affect the “greenness” of photoreactions. In general, photochemical procedures require the use of dilute conditions (from 5×10^{-3} to 5×10^{-2} M of the limiting substrate), in order to allow light to penetrate into the solution to a significant depth for making molecules absorb and react, resulting in a high environmental (and economical) impact of the procedure. On the other hand, higher concentrations often lead to a lack of selectivity, because of undesired secondary reactions involving both reagents and primary products. Furthermore, since most photoprocesses involve the use of artificial light sources, the electrical supply needed has a strong impact on both the environmental and the economical cost of the reaction, and constitutes the main limitation to the industrial application of photochemical reactions, except when photons are used in substoichiometrical ratio (e.g., photopolymerization or photo-initiated halogenation) [10]. In addition, the energy required by the cooling systems of several artificial light sources (especially high and medium pressure Hg lamps) must be taken into account.

From all these considerations, it appears clear that the concepts of photochemistry and green chemistry do not necessarily complement each other. The still pending question is: “how to employ a green reagent (photons) in green processes?” In order to satisfy the four conditions presented earlier, a detailed analysis of all chemicals involved in the reaction (including reactants, catalysts, solvents, and additional materials for workup and purification procedures) should be carried out and then followed by the minimization of the environmental hazards. Recent works evaluated in parallel photochemical and thermal pathways to some different synthetic targets, finding that both environmental and economical cost of the two alternative

routes are almost comparable [11]. What really matters is the fact that photochemical methods can be optimized more easily, by shifting toward less noxious solvents or, at least, by adopting solvent recycling. It should be noted that the term “synthetic process” includes all the reaction steps, including workup and product purification. From this point of view, large-scale reactions would be desirable, due to the possibility of using more eco-friendly purification methods, such as recrystallization or distillation, rather than column chromatography (that involves large amounts of silica gel or alumina, as stationary phase, and a high volume of eluant). With regard to the reduction of energy supply for artificial lamps, some advances have been reported, based on increased light absorption by the starting substrates. For example, Booker-Milburn has recently proposed a multigram scale flow reactor, in which the solution is driven around a water-cooled immersion well by the means of an high-performance liquid chromatography (HPLC) pump. This facility has been tested on a $[2 + 2]$ cycloaddition between 1-hexyne and maleimide (to give the bicyclic adduct **1**, Scheme 9.1) and on the synthesis of azepine **2** by intramolecular photocyclization (Scheme 9.1). Some hundred grams of both photoproducts were isolated after 24 h of irradiation [12].

In the last years, several photochemical processes have been proposed or, often, rediscovered as green methods. In the following sections, a series of examples of these innovative procedures and optimized technologies for carrying out “green synthetic photochemistry” will be presented. The best way of minimizing the environmental impact of photochemical reactions is to remove the solvent, and Sections 2.1

SCHEME 9.1 The continuous flow photoreactor engineered by Booker-Milburn (see Ref. [12]) employed for the synthesis of bicyclic compounds **1** and **2**. (From Hook, B.D.A. et al., *J. Org. Chem.*, 70, 7558, 2005. With permission.)

through 2.3 will be dedicated to this approach. When solvent is necessary for the reaction, more eco-friendly media can be used, as shown in Section 2.4. As far as the energy is concerned, the use of solar light clearly represents the ultimate choice (Section 2.5).

The selected examples have been classified into the previous sections according to what we consider their peculiar feature, even if most of them could be included in different categories.

9.2 Sustainable Methodologies in Photochemistry

9.2.1 Solvent-Free Reactions

As predictable by the use of dilute conditions, the environmental cost of photochemical procedures is mainly due to the solvent. Optimization of solvent free photochemical reactions is still considered a challenge in organic synthesis, and in most cases the preferred route to make ecosustainable chemical processes. Unfortunately, the close dependence existing between the reactivity of photo-generated intermediates and the physical and chemical properties of the solvent, often affects the outcome of such optimization. Nonetheless, several approaches have been developed to overcome the previously mentioned limitations.

When a liquid reactant is involved, it may act as both substrate and solvent. This expedient was first used by Paternò, at the beginning of the twentieth century, studying the photoreactivity of carbonyls in the presence of olefins [7b]. More recently, the photocatalyst 9-phenyl-10-methyl-acridinium perchlorate (5×10^{-3} M) was dissolved directly into benzyl alcohol, which was then oxidized by molecular oxygen with a quantum yield of 0.35 [13].

Rubiginones are presently investigated as potential drugs for the treatment of AIDS and Alzheimer's diseases. The key step in the synthesis of Rubiginone C₂ (**3**), for example, is the photo-induced one-step desilylation of a protected hydroxyl group, followed by its oxidation to a carbonyl and aromatization. Noteworthy, the reaction takes place under solvent-free conditions and using sunlight as the light source (Scheme 9.2) [14].

In solvent-free reactions, zeolites have been widely used as organic microenvironment, to improve the process selectivity [15] in the photogeneration of several reactive intermediates [16]. The photorearrangement of 3,5-diphenyl-1,2,4-oxadiazole, for example, has been studied in different zeolites, achieving selectively the 1,3,4-oxadiazole isomer (**4**) in 90% yield [17], in contrast with the large number of possible pathways observed in solution (Scheme 9.3).

Photooxidation of alkanes has been investigated by Blatter: irradiation of cyclohexane, loaded into NaY zeolites, with visible (blue or green) light afforded cyclohexanone selectively, with a high consumption of the starting material [18]. In some cases, zeolites are able to force the reaction toward a completely different pathway, with respect to what happens in solution. This is the case for stilbenes,

SCHEME 9.2 Synthesis of Rubiginone C₂ **3**.

SCHEME 9.3 Photorearrangement of 3,5-diphenyl-1,2,4-oxadiazole in zeolites.

which in Y zeolites are successfully oxidized to the corresponding benzaldehydes, rather than to the endoperoxide products usually observed in dichloromethane solution [19].

9.2.2 Photoreactions in Polymeric Matrix

This approach has been employed mainly in photo-oxidation processes. Photo-oxygenations involving singlet oxygen ($^1\Delta_g$) are appealing reactions in terms of green chemistry, involving only air (or, at least, oxygen) and a dye, as photosensitizer, together with the substrate. Furthermore, the commonly employed dyes absorb significantly in the visible part of the spectrum, allowing the use of sunlight irradiation. Unfortunately, singlet oxygen is a long-lived species only in problematic solvents, such as chloroform or carbon tetrachloride, and at the end of the reaction the dye has to be removed, either by column chromatography or distillation. These limitations have been recently overcome by the use of sensitizers immobilized on a polymeric matrix (by adsorption or covalent bonding), following an approach developed by Griesbeck and coworkers. A photosensitizer formed by *meso*-tetraphenylporphyrin (TPP) or tetratolylporphyrin (TTP), embedded in polystyrene matrix, was applied to the solvent-free oxygenation of sorbic alcohol, to give the corresponding endoperoxyde in high yields [20]. In the same way, less reactive β -pinene (**5**, Scheme 9.4), which is employed as precursor in the industrial synthesis of myrtenol, was converted selectively to hydroperoxide **6** and no side products were observed, even at high conversions, in contrast to the analogous liquid phase reaction. The optimized procedure is extremely simple: immobilization of the dye is carried out by swelling polystyrene particles in a solution of the dye in ethyl acetate, followed by solvent evaporation. The substrate is adsorbed onto the solid phase in the same way, then irradiated in a Petri dish (see Scheme 9.4) and the resulting product is recovered by washing with ethanol. With liquid reagents, loading is carried out directly, without any solvent. It should be underlined that the dye is used only in 0.01% M with respect to the reactant, and as much as 1 g of product can be achieved for every gram of employed polystyrene beads.

Alternatively, beads of tetrastyrilporphyrin (TSP) copolymerized with styrene and divinylbenzene have been employed for the synthesis of several peroxides and endoperoxides (including 1,2,4-dioxazole and hydroperoxides). It should be noted that this sensitizer has a high photooxygenation turnover number (3000) and can be efficiently recycled, without any dye losing or bleaching [21].

SCHEME 9.4 (See color insert.) Photosensitized oxidation of β -pinene **5**. (From Griesbeck, A.G. and Bartoschek, A., *Chem. Commun.*, 1594, 2002. With permission.)

SCHEME 9.5 Photosensitized synthesis of Juglone **7**.

1,5-Dihydroxy-naphthalene was oxidized to pharmacologically active Juglone (**7**), by immobilizing rose bengal on calcium alginate beads. The solvent used to solubilize the reactant and to recover the oxidized product (*tert*-amyl alcohol) was recovered and reused for further cycles (Scheme 9.5) [22].

Maldotti et al. employed iron(III) porphyrins, caged in NAFION membranes, as sensitizers for sunlight-induced allylic oxidation of cycloalkenes to the corresponding alcohols and ketones. Interestingly, the solvent-free process results in a satisfying turnover number (>1000) and efficiency (about 10 times higher than in alcoholic solution) [23]. Scorrano et al. [24] reported the solvent-free benzylic oxidation of aromatics (such as ethyl benzene, cumene, and indane) by a fluororous-tagged decatungstate ($[\text{CF}_3(\text{CF}_2)_7(\text{CH}_2)_3]_3\text{CH}_3\text{N})_4\text{W}_{10}\text{O}_{32}$), embedded on Hyflon membranes.

9.2.3 Solid-State Photoreactions

Since the birth of organic photochemistry, solid state conditions have been largely employed in synthetic processes, as demonstrated by the [2 + 2] dimerization of anthracene and thymoquinone, described by Liebermann and Fritzsche, respectively [6]. Apart from the environmental advantages, photoreactions in crystals often lead to a completely different pathway, with respect to those observed in solution, and sometimes increase selectivity. In a recent example, it was found that head-to-tail arranged crystals of catecholamine **8** underwent efficient photodimerization (dimer **9** in Scheme 9.6a) [25], while an *E/Z*

SCHEME 9.6 [2 + 2] photodimerization of (a) catecholamine **8** and of (b) A_{2A} adenosine receptor antagonist **10**.

SCHEME 9.7 Solid state, enantioselective route to (a) (+)-lactam **13** and (b) β -thiolactam **15**.

photoisomerization was the only observed path in methanol. An analogous behavior has been reported for 8-styryl-xanthenes. In particular, solid state photolysis of molecule **10** (a potent A_{2A} adenosine receptor antagonist, that has been proposed for the treatment of Parkinson's disease) gave selectively the [2 + 2] dimer (**11**), contrary to the isomerization observed in dichloromethane solution (Scheme 9.6b) [26].

The stereochemistry of a reaction can be strongly improved by adopting solid state conditions. For example, lactam (+)-**13** has been easily synthesized through a Norrish-Yang path, by irradiation of an hexane suspension of *N,N*-dialkylglyoxamide chiral salt crystals (**12**) [27]; the desired product was obtained in high yield and with a satisfying enantiomeric excess (99%, Scheme 9.7a). Sometimes, non-chiral molecules are able to adopt a chiral conformation in the crystal lattice, and the resulting molecular environment offers an opportunity for asymmetric induction in the photoreaction. A representative example is the enantioselective synthesis of β -thiolactam **15**, which has been accomplished by irradiation of the relative nonchiral α,β -unsaturated thioamide **14**. The product was formed in excellent yield (96% based on thioamide consumption) and the enantiomeric excess was just slightly affected, when increasing the substrate conversion (Scheme 9.7b) [28].

A smart crystal-to-crystal approach to the decarbonylation of ketones was proposed by Garcia-Garibay and is probably the most significant "green" attempt in the field of solid state photochemistry. In his report, irradiation of finely powdered crystals of 1,3-diphenylacetones, sandwiched between two Pyrex plates, afforded the corresponding 1,2-diphenylethanes in satisfactory yields [29]. Solid state decarbonylation of dicumylketone (**16**), to give dicumene (**17**), has been ingeniously scaled up to 10 g of reactant; in this case, an aqueous suspension of **16** has been irradiated for 19 h, in a flow-reactor made up of a 5 L vessel and a submersible pump, which circulated the suspension through the immersion well (Scheme 9.8) [30]. At the end of the reaction, **17** was easily isolated by filtration through a Whatman cellulose filter.

The same procedure was applied also to six different di-*p*-carboxydiphenyl-2,4-dimethylpentanone ammonium salts (**18**). Decarbonylation occurred in quantitative yield, after only 6 h of irradiation with a Hg medium pressure lamp (Scheme 9.9) [31].

The presence of coordinative bonds (e.g., hydrogen bonds) in the solid state has been exploited in order to enhance stereoselectivity, as demonstrated by MacGillivray [32] in the dimerization of stilbene. For example, assembly of the [resorcinol*(*trans*-1-(4-pyridyl)-2-(4-chlorophenyl)ethylene)₂] complex in a head-to-head geometry and subsequent irradiation resulted in a regio-controlled photodimerization, giving the resulting cyclobutane as a single diastereoisomer.

The same strategy has been exploited in the synthesis of *para*-cyclophanes, a class of molecules that find application in material sciences. In this case, cocrystallization of 5-benzyl-resorcinol with 1,4-bis[2-(4-pyridyl)]

SCHEME 9.8 (See color insert.) Solid-state photo-decarbonylation of dicumylketone **16** in a photochemical flow reactor. (From Veerman, M. et al., *Org. Lett.*, 8, 2615, 2006. With permission.)

SCHEME 9.9 Solid-state photo-decarbonylation of *p*-carboxydiphenyl-2,4-dimethylpentanone ammonium salts **18**.

ethenyl] benzene (1,4-bpeb) afforded a four-component complex $[(\text{Bn-resorcinol})_2 \cdot (1,4\text{-bpeb})_2]$, **19** in which the two dienes are already oriented for a double cycloaddition. UV irradiation of the complex afforded the crowded derivative **20**, in a completely stereospecific manner and in 100% yield (Scheme 9.10).

Even supramolecular systems with 3D regularity can be synthesized through solid state photochemical self-assembly. It is the case of 1,2-bis(4-pyridyl)ethylene and benzene 1,2,4,5-tetracarboxylic acid co-crystals (**21**), which dimerized and gave a pure diastereoisomer, in 100% yield. Moreover, when the product was ground with a small amount of dimethylsulfoxide, a nanoporous supramolecular solid with a large channel structure was obtained (**22**, Scheme 9.11) [33].

9.2.4 Photoreactions in Eco-Friendly Solvents

Many photochemical reactions have been discovered and developed when the chronic toxic effects of several organic solvents were unknown or, at least, underestimated. The definition of "green solvent" for a chemical reaction has been recently discussed in two independent works, by Capello [34] and Alfonsi [35].

SCHEME 9.10 Double stereospecific [2 + 2] cycloaddition of [(Bn-resorcinol)₂ · (1,4-bpeb)₂] (**19**).

The combined use of green metrics tools (such as EHS or LCA methods) and, of course, a bit of common sense allowed the evaluation of solvents impact on different general areas, such as the safety of workers, of processes and of the environment. This assessment takes into consideration several easily available parameters, such as toxicity, carcinogenicity, flammability, and eco-toxicity. Starting from all these data, a list of undesirable solvents has been established, including high flammable media (such as pentane and diethylether), carcinogenic (as benzene, carbon tetrachloride and chloroform), and highly toxic ones (e.g., *N,N*-dimethylformamide). Since these solvent selection schemes have been developed for thermal reactions, their application to photochemistry suffers from some limitations. Some common replacements, for example, toluene for benzene, cannot be done for photochemical transformations due to reactivity issues. Other problems may derive from low transparency of the reaction medium or its potential sensitization role (as in the case of acetone).

9.2.4.1 Reactions in Water or in Aqueous Mixture

Cheap and nontoxic water is obviously the ideal solvent for green syntheses, although its use is strongly limited by the low solubility of most organic compounds in it. Nevertheless, a few examples of photochemical transformations in water are available in the literature. Among these, the visible light-induced benzylic bromination of methylbenzenes by *N*-bromosuccinimide has been reported; either 40 W bulb irradiation or sunlight can be used for this reaction. Despite the prejudices about workup and purification procedures in water, the previously mentioned method is extremely simple: the starting methylbenzenes (see, e.g., the bromination of benzoic ester **23**, Scheme 9.12) form a layer "on top of the water phase," but as soon as they are brominated, their specific weight increases and the organic phase sinks to the flask bottom. The only by-product formed is succinimide, which is soluble in water and can be smoothly removed (by phase separation or filtration) from the hydrophobic organic product [36].

Another reasonable alternative is the partial substitution of organic solvents with water, according to the rule that, the higher the water percentage in the reaction medium, the lower environmental cost. Photoinduced cyclization of phthalimide derivatives by Griesbeck et al., for example, used a water-acetone mixture as solvent. The mechanism included an initial photoinduced electron transfer, followed by decarboxylation, and led to a wide range of useful synthetic targets, such as pyrrolizidine- and indolizidine-based alkaloids, benzodiazepines, and aristolactams [37]. The process was efficiently scaled up,

SCHEME 9.11 Synthesis of supramolecular system **22** via diastereomeric dimerization of 1,2-bis(4-pyridyl)ethylene and benzene 1,2,4,5-tetracarboxylic acid co-crystals (**21**).

SCHEME 9.12 Visible-light-induced bromination in water.

by means of a photoreactor equipped with a 3 kW XeCl excimer lamp, which is an almost monochromatic (308 nm, Scheme 9.13) and highly efficient light source (the electrical power to light conversion yield is about 10%) [38]. Irradiation of a suspension of potassium carboxylate **24** (Scheme 9.13) in neat water, followed by partial evaporation and filtration of the resulting precipitate, afforded the cyclized derivative **25** in 82% yield; noteworthy, the purity of the isolated product was remarkably higher than the one obtained with traditional photochemical methods [39].

SCHEME 9.13 (See color insert.) Photochemical cyclization of potassium carboxylate **24** carried out in a 3kW XeCl excimer lamp equipped photoreactor. (From Griesbeck, A.G. et al., *Green Chem.*, 1, 205, 1999. With permission.)

SCHEME 9.15 Synthesis of (a) γ -benzyltetrahydrofurans and (b) benzonitriles via triplet phenyl cation.

benzonitriles are usually accessible through Sandmeyer reaction or Pd-catalyzed cross-couplings, our protocol avoids both the use of transition metal catalysts and the protection of sensitive functional groups (such as phenol or aniline moieties) [41].

Following another strategy, photolysis of pyrene with sodium cyanide in a benzonitrile/water 1:100 emulsion led selectively to 1-cyanopyrene in 83% yield [42].

Regarding alkylations, unsaturated aldehydes were converted to γ -butyrolactols or lactones in aqueous media, by means of different water-soluble photocatalysts (e.g., disodiumbenzophenone disulfonate [BPSS] or sodium 4-benzoylbenzoate). Irradiation of 2-hexenal in 50% aqueous methanol afforded lactol **30** in good yield and on gram scale (Scheme 9.16a) [43]. Interestingly, 1,4-alkylation took place selectively, in contrast with the competition between 1,4- and 1,2-alkylation observed in the analogous thermal reaction.

The same approach has been recently applied to the solar synthesis of γ -lactones, as well as of monoprotected succinaldehydes; thus, exposure of an isopropanol/water 1:1 solution of maleic acid to moderately concentrated sunlight (by means of SOLFIN facility, see the following text) gave terebic acid (**31**) in 75% yield (Scheme 9.16b) [44].

SCHEME 9.16 (a) Photocatalyzed alkylation of 2-hexenal in 50% aqueous methanol; (b) sunlight-induced photocatalyzed route to terebic acid **31**.

SCHEME 9.17 TiO_2 photocatalyzed oxidation of 4-methoxybenzyl alcohol.

The use of surfactants able to form micelles with hydrophobic cores is a feasible way to overcome the low solubility of organic reactants in water. For example, micelles formed by *N,N*-dimethyl tetradecylamine-*N*-oxide (DTAO) can host iron(III) *meso*-tetrakis(2,6-dichlorophenyl)porphyrin [Fe^{III} (TDCPP)] sensitizer, resulting in a microheterogeneous catalyst for sunlight-induced photooxidations. Under these conditions, epoxidation of cyclooctene was carried out with selectivity higher than 90% [45].

Another alternative medium is represented by aqueous suspensions. Irradiation of benzyl alcohols in a colloidal suspension of TiO_2 proved to be a promising procedure for their selective oxidation to carbonyls, avoiding the use of harmful conditions, such as high temperature or pressure, as well as of noxious oxidants, like chromate or permanganate salts. Palmisano, in particular, reported a home-made TiO_2 photocatalyst for the selective oxidation of *p*-methoxybenzyl alcohol (chosen as a model substrate) to *p*-methoxybenzaldehyde, in water. Although there is a possibility of generating unstable highly oxidizing species, such as hydroxyl radicals, only traces of benzoic acid were detected as a side product. In addition, oxidation yields obtained with the home-prepared titanium dioxide catalyst were always higher than with the commercially available TiO_2 (Scheme 9.17) [46].

9.2.4.2 Reactions in Eco-Friendly Organic Solvents

When water cannot be used as reaction medium, the replacement of an environmentally problematic solvent is possible by using a chemically similar organic medium, with a lower environmental impact. Greener alternatives are represented by *n*-heptane (instead of highly flammable *n*-pentane and more toxic *n*-hexane), ethanol (which is renewable), methanol, and acetone (that are cheap and scarcely toxic). Nevertheless, chemists should remember that the replacement must not affect other important parameters of the reaction, such as its economical cost and efficiency, with the aim of achieving an industrial scale-up of the procedure. Alkoxyamines, for example, are efficient carbon-based radical precursors for polymerization procedures and organic synthesis, and one of them (BlockBuilder 34, Scheme 9.18) has been produced on large scale by Arkema. Due to its low dissociation temperature (about 30°C), photochemistry was the only tool that allowed a clean synthesis of this product.

The optimized procedure proposed by Guillauneuf et al. involved the photodecomposition of azoderivative 32 and dithiocarbamate 33 in neat ethanol. In contrast to the previously reported photochemical syntheses of alkoxyamines, the latter reagent acted as a catalyst, was added in substoichiometric amount with respect to the azo-compound, and was finally recovered and reused, lowering production costs [47].

The synthesis of Vitamin D₂ (Calciferol), by irradiation of Ergosterol and following thermal rearrangement, is probably the most important photochemical process that has found industrial application. The multigram preparation of this bioactive compound, which balances the *in vivo* absorption of calcium and phosphorus, was scaled up to 200 L by Jike et al., through a batch photoreactor. Irradiation of a highly concentrated ethanol solution (1.4 g/L) of Ergosterol led to an excellent yield of Vitamin D₂ thermal precursor (pre-Calciferol, 84% based on consumed Ergosterol). Four of the aforementioned batch photoreactors were connected in series and the resulting flow-system afforded a high conversion of starting Ergosterol (>70%) and a satisfying production of pre-vitamin D₂ (62% yield, 62% selectivity) [48].

Acetone proved to be a good solvent for photochemical reactions too. The synthesis of 1-indanone 36 (a precursor of Dopenezil, 37, used in the treatment of Alzheimer disease), for example, by photolysis

SCHEME 9.18 Synthesis of carbon-based radical precursor for polymerizations BlockBuilder **34**.

SCHEME 9.19 Photolysis of phenacyl ester **35** as a key step in the synthesis of Dopenezil **37**.

of the corresponding phenacyl ester **35** has been tested in several solvents, of which acetone showed the highest yield (90% yield, Scheme 9.19) [49].

Light-induced hydrolysis of Schiff bases in aqueous acetone was applied to the synthesis of antitumor agent **39**. This approach led to quantitative deprotection of imine **38**, after less than 1 h of UV irradiation; encouraging results were obtained also by exposing the solution directly to sunlight, although with significantly longer exposition times (15 days, Scheme 9.20) [50].

With regard to alcoholic media, photoreduction of imines to the corresponding amines was carried out in 2-propanol, with an excess of triethylamine in order to avoid decomposition of the desired product. Under these conditions, a variety of aldimines were selectively reduced in good yields [51].

SCHEME 9.20 Photochemical hydrolysis of Schiff bases in aqueous acetone.

Photodehalogenation of aryl chlorides and fluorides, either in neat 2-propanol or in the presence of H_3PO_2 , has been developed as a mild alternative to the use of hydrides or of low-valence metals as reductants [52].

9.2.4.3 Reactions in Nonclassical Solvents

Room-temperature ionic liquids (ILs) are low-melting salts, which have recently attracted much interest in the field of green synthesis: their negligible vapor pressure prevents solvent emission and allows their reuse [53]. The main limitation to the use of ionic liquids in photochemistry is the high spectrophotometrical purity needed, which would require particular care during their purification.

The one-pot synthesis of fluoroimidazoles, such as **40**, from the corresponding amino derivatives has been successfully carried out in 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF₄]) and the desired products were isolated in moderate overall yields (about 60%) after 24 h of irradiation. This reaction was carried out at 0°C to prevent photodecomposition of the medium (observed before at higher temperatures) and to maintain its purity at a reasonable grade (Scheme 9.21) [54].

As far as a photoreductive process is concerned, Reynolds et al. [55] reported several amine-mediated reductions of benzophenone moieties in [bmim][BF₄], to selectively give the corresponding benzhydrol. The process was performed three times in the same solvent, without any influence on both product yield and chemoselectivity.

Sometimes, ionic liquids allow an enhanced chemoselectivity, compared to usual solvents. The singlet oxygen-mediated oxidation of phenol in ethylammonium nitrate, for example, was found to give only benzoquinone in nearly 60% yield, whereas the same reaction in water afforded a mixture of quinone and quinhydrone [56].

Among nonclassical solvents, nonflammable and nontoxic supercritical CO₂ has recently attracted much attention, as demonstrated by the singlet oxygen-induced synthesis of ascaridole from α -terpinene: in 140 bar sCO₂, the turnover efficiency of the photocatalyst (5,10,15,20-tetrakis(pentafluorophenyl)porphyrin, TPFPFPP) is higher than in CCl₄ (16 vs. 7). Moreover, the high solubility of oxygen in this medium allowed the use of a near equimolar concentration of the oxidant with respect to α -terpinene [57].

9.2.5 Sunlight-Induced Syntheses

Solar radiation is the “green” energy source *par excellence*, since it is free, renewable, and it does not produce greenhouse gases. Plants, for example, store sunlight into chemical energy through the photosynthetic process and represent the ideal green laboratory, in which useful biomass (mainly sugars) is produced from nontoxic reagents (carbon dioxide, water, mineral salts) under mild conditions, with oxygen as the only side product.

Unfortunately, the use of solar energy in human-made reactions is affected by several limitations, such as weather conditions, geographic location, and day/night alternance. In addition, only a few organic compounds absorb significantly in the visible region of the spectrum, thus limiting the versatility of the method.

For all these reasons, it is not surprising that sunlight (which, in the dawn of photochemistry, was obviously the only available light source) has been quickly replaced by artificial lamps. The synthetic potential of solar chemistry, however, was again recognized in the 1980s and 1990s, thanks to the works performed in Almería and Cologne by Scharf and coworkers [58].

SCHEME 9.21 One-pot synthesis of fluoroimidazoles in [bmim][BF₄].

9.2.5.1 Reactions under Nonconcentrated Sunlight

Despite the low intensity of solar radiation and its dependence on weather conditions, photochemical reactions can often be carried out in reasonable times and good yields, simply by exposing the vessel to natural light on a window ledge. In the following, some representative cases are shown, which constitute only a small fraction of all the photochemical processes that are actually accessible in this way; at least in principle, all the reactions mentioned here could be smoothly scaled up, simply by increasing batch dimensions.

Photopinacolization of aromatic ketones was one of the first photochemical processes observed by Ciamician and Silber, and then investigated for differently substituted benzophenones by Cohen in 1920 [58b]. Recently, a general procedure for the photoreductive coupling of aromatic aldehydes and ketones to 1,2-diols has been reported. Such a protocol represented a valid green alternative to thermal methods, in particular when benzaldehyde was reduced, allowing to reuse the solvent (2-propanol and acetone) three times, without significantly affecting the process efficiency [59].

Photoinduced elimination of a Ph_2S group in *N*-conjugated sulfinimines was adopted for the synthesis of pyrrolo[2,3-*d*]pyrimidine-2,4-diones such as **41** (Scheme 9.22) [60]. All the desired heterocycles were obtained in closely quantitative yields, after short illumination times (from 40 min to 3.5 h), while the analogous thermal pathway failed, even under harsh conditions (refluxing toluene for 30 h).

Since most organic compounds do not absorb UVA radiation at all, the use of photocatalysts that absorb light instead of the substrates plays a key role in the development of sunlight-mediated syntheses. TiO_2 -photocatalyzed functionalization of nitrogen-based protonated heterocycles (such as quinoline, lepidine, and quinoxaline) by formamide (Scheme 9.23, compound **42**) has been reported by Caronna et al. Products were obtained in moderate to excellent yields by exposing the reaction mixtures to sunlight for less than 15 h [61].

In the last years, tetrabutylammonium decatungstate (TABDT) emerged as a versatile photocatalyst for C–H activation of a wide variety of substrates (including aldehydes, cyclic ethers, amides, and alkanes), followed by their addition to electron-poor olefins. Our research group has recently reported scale-up and environmental optimization of these processes: in the reaction reported here, for example, compound **43** was obtained in high selectivity and efficiency, simply by exposing a Pyrex vessel with the reaction mixture on a suntrap (e.g., a window ledge), for a few days. Since the absorbing species is TABDT, UVA-transparent reactants were used in high concentrations (up to 0.5 M), greatly increasing the process efficiency (about 10 g/exposed dm^2 , Scheme 9.24) [62].

Visible light irradiation of $[\text{Ru}^{\text{II}}(\text{bipy})_3]^{2+}$ ($\lambda_{\text{max}} = 452 \text{ nm}$) led to a charge-separated intermediate ($[\text{Ru}^{\text{III}}(\text{bipy})_3]^{2+}$), a powerful photoredox catalyst, that is able to either oxidize or reduce a variety of organic derivatives. As an example, [2 + 2] cycloaddition of acyclic enone **44** with methyl-vinyl ketone

SCHEME 9.22 Photochemical synthesis of pyrrolo[2,3-*d*]pyrimidine-2,4-diones.

SCHEME 9.23 Photocatalyzed functionalization of 2-methylquinoline by formamide.

SCHEME 9.24 Sunlight-induced photocatalyzed acylation of electron-poor olefins.

SCHEME 9.25 [Ru^{II}(bipy)₃]²⁺ photocatalyzed synthesis of functionalized cyclobutanes.

was reported, through outdoor illumination, leading to the corresponding cyclobutane derivative (**45**) with an excellent diastereoselectivity (*anti/syn* ratio > 1:10, Scheme 9.25) and in satisfactory yield [63]. Notably, using acyclic bis(enones), intramolecular cyclization took place almost quantitatively but favoring the anti diastereoisomer [64].

The gram-scale triplet-sensitized *E/Z* isomerizations of several molecules including enones and stilbenes have been performed in an ingenious floating solar reactor, to avoid the use of circulating water. Exposition of an ethanol solution of dinitrile **46** and rose bengal to sunlight for only 20 min gave the corresponding *cis*-isomer (**47**) in 71% yield (Scheme 9.26) [65].

9.2.5.2 Reactions under Concentrated Sunlight

In one-sun solar collector reactors (e.g., the pilot plant designed by Schenck, for the synthesis of Ascaridole, see Section 9.1), light was absorbed directly, without being previously concentrated. Due to the low intensity of the radiation, a large exposition area would be necessary to carry out in reasonable times reactions that need short wavelengths (<450 nm) or that are characterized by low quantum yields. During the last decades, more elaborated reactors enabling sunlight concentration were built with a considerable increase of the space–time yield. The SOLFIN (SOLar synthesis of FINE chemicals) and the CPC (Compound Parabolic Collector) facilities, for example, employ moderately concentrated sunlight (concentration factor [CF] = 2–3) for efficient gram-scale syntheses. Both of them consist of coaxial cylindrical mirrors, tilted toward the sun, that collect and concentrate light. The photolyzed solution is placed in the focus line and circulated by means of a centrifugal pump.

SCHEME 9.26 (See color insert.) Sunlight-induced photosensitized *cis-trans* isomerization of dinitrile **46**. (From Zhao, Y.P. et al., *Green Chem.*, 10, 1038, 2008; Zhao, Y.P. et al., *Green Chem.*, 11, 837, 2009. With permission.)

SCHEME 9.27 Sunlight-induced synthesis of tricyclic derivative **49**.

The regio- and stereoselective synthesis of cyclobutane rings, through $(2\pi + 2\pi)$ photochemical addition between 2-acetoxy-1,4-naphthoquinone (**48**) and 1,1-diphenylethene (or styrene), was performed by means of a parabolic through collector, both in acetonitrile and in methanol, giving an interesting building block for the synthesis of anthraquinone (**49**, Scheme 9.27) [66].

The cyclization product was obtained in high purity (>99%), simply by removing the solvent *in vacuo* and then recycling it. The quinone concentration could be increased to 6% w/v, without affecting reaction efficiency and selectivity, allowing the successful scale up of the reaction to industrial level.

Photooxidation of naphthols has been deeply investigated by Mattay and Oelgemöller. They achieved the synthesis of pharmaceutically active Juglone (**7**, see also Section 2.2) by illumination of an isopropanol or acetone solution of 1,5-dihydroxynaphthalene, in the presence of Methylene Blue or rose bengal as photosensitizers. The yield of photooxidized product was always higher than 70%, even under cloudy weather conditions. Solid-supported rose bengal was also tested, showing similar yield of Juglone, although the substrate conversion yield was significantly lower [67]. Pioneering experiments on multigram syntheses were performed in Almeria (Spain) by Scharf and coworkers, in the early 1990s, by means of the SOLARIS reactor engineered by G. Schneider (DLR, Cologne, Germany) [9]. That parabolic through collector employed a MAN Helioman module, which is able to track the position of the sun and to simulate the concentration of 20 suns on the absorber tube. The solution was pumped through the recirculating system, until the desired degree of conversion was achieved; the circulating loop had an operating volume between 35 and 70 L. In 1991–1992, several reactions were tested, in order to check the feasibility

Sensitizer = Rose bengal or methylene blue

SCHEME 9.28 Singlet-oxygen-mediated oxidation of furfural to 5-ethoxyfuranone (**51**).

of solar photochemistry under these conditions. Singlet oxygen-mediated production of 5-hydroxyfuranone (**50**) from easily available and cheap furfural, in ethanol and in the presence of a photosensitizer gave high yields (>95%) and only traces of 5-ethoxyfuranone (**51**, <3% yield, Scheme 9.28) as by-product.

The SOLARIS plant was dismantled at the end of 1992 and rebuilt in Cologne (Germany). A few years later, the PROPHIS plant (see Scheme 9.29a) was projected by the German Aerospace Center (DLR) in Cologne; this new reactor (concentration factor, CF = 15) supported a reaction volume that varied from 35 to 120 L and was equipped with four parabolic troughs (see Scheme 9.29b).

A set of test reactions were performed with PROPHIS, confirming its synthetic performance [68]. The atom economic synthesis of 2-phenyl-pyridine from acetylene and benzonitrile, in the presence of CpCoCOD as photocatalyst, was particularly efficient when done by solar exposure, while this photocatalyst is not stable under artificial UV light [68]. Among singlet oxygen-mediated oxidations, one of the most industrially relevant is the production of Rose Oxide (**53**) fragrance. The key step is rose bengal sensitized Schenck-ene addition of singlet oxygen to citronellol (**52**), which leads to a mixture of isomeric hydroperoxides (Scheme 9.30). Using PROPHIS, peroxydation of citronellol in 2-propanol

SCHEME 9.29 (See color insert.) (a) The PROPHIS plant scheme, projected by German Aerospace center (DLR) in Cologne; (b) an image of the PROPHIS plant equipped by four parabolic troughs as light collector. (From Schiel, C. et al., *J. Green Chem.*, 3, 224, 2001. With permission.)

SCHEME 9.30 Photosensitized route to rose oxide (53).

SCHEME 9.31 Sunlight-induced photochemical acylation of quinones.

showed an efficiency close to 1. After reduction by Na₂SO₃ and acid-base catalyzed cyclization, **53** was isolated in 55% yield [69].

The same fragrance was also synthesized in 82% yield by superoxide ion (O₂^{•−})-mediated oxidation; in this case, an aerated acetonitrile solution of citronellol and dehydroabietyl perylene diimide (ABIPER) as photosensitizer was exposed to concentrated sunlight (equivalent to 90–100 suns), by means of a Fix Focus FF 3.5 instrument, with a reflective area of 2.66 m² [70].

Radical-based acylation of quinones represents an eco-friendly alternative to Friedel–Crafts processes, in which aldehydes are used as sources of acyl radicals and quinones act both as formyl C–H bond activators and acyl radical acceptors. Since quinones absorb significantly above 300 nm, an alternative process based on concentrated sunlight has been recently proposed: using PROPHIS, naphthoquinone reacted with butanal, in a *tert*-butanol/acetone 3:1 mixture, and afforded the acylated product in high yield (90%, ca. 500 g for 80 L reaction mixture), after 3 days of exposition only. Photochemical acylation of benzoquinone by 2,4-dimethoxybenzaldehyde to give **54** was chosen as a model reaction to compare the use of either concentrated or direct sunlight (Scheme 9.31) and was carried out in three different reactors: PROPHIS loop (CF = 15), CPC (CF = 2–3), and a flat bed reactor (CF = 1). Although CPC does not track the sun (contrary to PROPHIS), it gave the best results in terms of substrate conversion (with an efficiency three times higher than PROPHIS) and it was found to be the less dependent on weather conditions, thanks to the possibility of using both direct and diffuse light [71].

9.3 Perspectives and Conclusions

With the overview of synthetic methods and technologies presented here, we intended to highlight the green potentialities of photochemistry. As shown earlier, recent literature evidences its skill to satisfy green chemistry principles, thanks to the use of solvent-free conditions or aqueous solvents and to the low energy demand (e.g., in sunlight induced reactions). The search for sustainable and scalable photochemical procedures showed some significant advances in the past few years, including the development of new and more efficient flow reactors, solar collectors and micro-reactors, whose applications have been recently reviewed [72,73].

Apart from green synthesis, photochemistry contributes strongly to other fields of sustainable development, such as production of energy by conversion of solar light into electricity [74] or chemical fuels [75]. The development of artificial photosynthetic systems emerged in the last decades as one of the most significant challenges for chemists [76]. Furthermore, photochemistry represents a useful solution to the increasing demand for depollution technologies, mainly through heterogeneous photocatalysts (such as TiO_2) [77].

That being so, we are confident that the evolution of photochemistry, evidenced by the previous selected examples, will greatly contribute to the future progress of green chemistry.

Acknowledgments

We are grateful to Dr. Winfried Leibl, Dr. Joseph H. Hughes (CEA Saclay, France), Prof. Maurizio Fagnoni, and Dr. Davide Ravelli (University of Pavia, Italy) for fruitful discussion. S.P. acknowledges MIUR, Rome (FIRB-Futuro in Ricerca 2008 project RBFR08J78Q) for financial support.

10.1 Introduction

Green chemistry is a multidisciplinary concept that has emerged over the past two decades, commencing in academia and research and development, which has subsequently impacted greatly on the chemical industry.^{1,2} The growth of interest in green chemistry has been driven in particular by the increasing desire for sustainable developments and reduction of carbon dioxide emissions. This has led to increasing interest in environmentally friendly technologies and the adoption of green chemistry approaches in both academia and industry.²⁻⁴ The use of light as a “clean reagent” has been reported and indicates that light (in particular, solar light) may provide a green access to chemical reactions.⁵ These concepts have been examined in academia over the past century; however, they have only recently come to the fore in mainstream applications.

10.2 Photochemistry and Green Chemistry

In general, synthetic photochemistry has had little impact in industry, although some examples of photochemical processes exist.⁶ This low impact is attributed to the high running costs of the commonly used light sources (energy demands and cooling), such as mercury or halogen lamps. Of the electrical

energy supplied, less than half is converted to light energy, resulting in a large quantity of wasted energy. The heat release of conventional lamps additionally causes significant cooling water needs. Another factor that limits the perceived greenness of photochemical processes is the typical reaction conditions. Photochemical reactions, in particular on the large scale, tend to use rather diluted conditions to enable light penetration through the entire reaction mixture.

The potential of photochemistry as a “clean” technology has been discussed by Bochet,⁷ who outlines the perceived disadvantages of photochemistry and some approaches to avoid these issues. Albini has discussed the relative merits of photochemistry compared to thermal synthesis using Environmental Assessment Tool for Organic Syntheses⁸ (EATOS) models.⁹ However, one failing of this model is that it does not include energy demand of the processes, which can be a considerable factor in the overall “greenness” of any process.¹⁰ From the EATOS values obtained, Albini concludes that the major drawback of photochemical methods compared to thermal processes is the concentration of photochemical solutions.

Despite these disadvantages, there are many advantages of photochemistry as a green technology, for example, the use of mild conditions and comparably low temperatures. Photochemical reactions (with the exception of chain reactions) can also be controlled with a “flick of a switch.” In addition, many photochemical processes demonstrate good to perfect atom economy, as the transformation is initiated by a photon, rather than an extra reagent.¹¹ The use of solar light furthermore provides an effective green route to fine chemicals.^{12,13}

The concept of photochemistry as a green technology is over 100 years old, as envisaged by Ciamician in the 1900s. At the International Congress of Applied Chemistry in New York in 1912, he presented his remarkable vision of “The Photochemistry of the Future”¹⁴:

“On the arid lands there will spring up industrial colonies without smoke and without smokestacks; forests of glass tubes will extend over the plains, and glass buildings will rise everywhere; inside of these will take place the photochemical processes that hitherto have been the guarded secret of the plants, but that will have been mastered by human industry which will know how to make them even more abundant fruit than nature, for nature is not in a hurry and mankind is”.

This eloquently foretells a key role for photochemistry in future industrial processes. Therefore, despite the advent of artificial light sources and other leaps in technology, it is not unexpected that mankind turns to the sun as a free energy and light source for solar chemical transformations and true “green” photochemistry.

10.3 Early Solar Studies

Solar chemistry is the earliest form of photochemistry, as photochemical transformations have occurred on earth since before human life came into existence. However, interest in synthetic organic photochemistry did not commence until the eighteenth century, when Joseph Priestly began his investigations into the chemical effects of light, leading to recognition of photosynthesis.¹⁵ Following this work, interest in photochemical transformations slowly increased, until interest peaked in the nineteenth and twentieth centuries. The earliest photochemical processes were all solar in nature, often consisting of jars of solution phase reagents allowed to stand in sunlight for days, weeks, and even months.

Giacomo Ciamician (1857–1922), whose work provides a wealth of information regarding solar chemical transformations, is regarded as the “father of organic photochemistry.” Together with Paolo Silber (1851–1932), he identified many types of photochemical reactions, in particular, ketone chemistry such as photoreduction (Scheme 10.1), photopinacolization, intramolecular cycloadditions (e.g., intramolecular [2 + 2] cycloaddition of carvone), and α - and β -cleavage.¹⁶

Following Ciamician’s death in 1922, McPherson stated in his obituary that “anyone visiting the chemical laboratory of the University of Bologna during the early part of the present [twentieth] century, could easily surmise the character of the researches being carried out in that laboratory; for the

SCHEME 10.1 Photoreduction of 1,4-benzoquinone in ethanol.

SCHEME 10.2 The Schönberg reaction.

exterior rear of the building was fitted with shelves and on these rested hundreds of bottles and sealed tubes of every description, all exposed to the sun's rays."¹⁷

Alexander Schönberg (1892–1985) was a German chemist who emigrated to Egypt prior to the Second World War. He is especially credited with the compilation of the first book on preparative organic photochemistry in 1958, which was revised and translated to English in 1968.¹⁸ Over the course of 20 years, he additionally carried out extensive studies of the chemical effect of sunlight. These included the reaction of aldehydes with phenanthraquinoneimine to form 2-hydroxyl-2,3-dihydrophenanthroxazole derivatives, photopolymerization of coumarins and related substances (in aqueous solutions), and photoaddition and photoreduction of aromatic ketones. The Schönberg reaction (also known as the Schönberg–Mustafa reaction) describes the cycloaddition of alkenes to orthoquinones (Scheme 10.2).¹⁹

10.4 Development of Solar Technology

The earliest photochemical experiments were carried out in glass flasks, which were exposed to natural light without cooling.^{15,17} However, there were hazards associated with this practice, in particular, early reports often stated that reaction mixtures were lost in windstorms or other incidents. In addition, the reaction mixtures were often placed in sealed containers, leading to a risk of explosion during exposure, such as gas evolution or evaporation of volatile solvents. Despite these risks, a wealth of solar chemical reactions were investigated under these primitive conditions. With the significant advances in lamp technology in the latter half of the twentieth century, photochemistry moved indoors and became a successful research area.⁶

The “indoor period” of photochemistry continued until the end of the last century, when rising oil prices and awareness of global warming led to a revolution in thought and a reemergence of interest in solar chemistry. To accompany this renewed interest in solar work, new reactors were designed, which could use non-concentrated and concentrated sunlight. Much of the new technology is based on modified reactors for energy production, for example, the parabolic trough-facility for organic photochemical syntheses (PROPHIS) reactor at the German Aerospace Centre (DLR) in Cologne, which is based on reactor design for solar-thermal applications.²⁰ The compound parabolic collector (CPC) reactor was designed for water treatment processes, but has since been adopted for use in synthetic applications.²¹

10.4.1 Non-Concentrating Reactors

Early photochemical studies simply required that a standard reaction flask be placed outdoors. However, a desire to achieve scale-up or higher conversions in a shorter time has led to the development of more suitable outdoor reactors. More advanced non-concentrating reactors have been developed, such as flatbed

FIGURE 10.1 (See color insert.) Flatbed and tube reactors at the DLR in Cologne.

or tube reactors (Figure 10.1), which can use both direct and diffuse sunlight.^{13a} The flatbed reactor type realizes a large surface area with a thin depth.

Other non-concentrating designs include free-falling film reactors, pressurized flat-plate reactors or solar ponds.²¹ A novel concept recently reported by Liu is the floating reactor (“lab on a surfboard”), which utilizes the ocean as a “heat sink” for cooling solar chemical transformations.²² This reactor effectively eliminates both cooling and irradiation costs for the process.

10.4.2 Concentrating Reactors

Reactors for concentrating sunlight were initially developed for solar energy production, such as the line-focus parabolic trough concentrator. This reactor design was easily modified for photochemical work, where the central tube is replaced with a transparent glass (e.g., Pyrex) tube through which the reaction mixture is passed. Many of these parabolic trough reactors are now in use for solar chemical applications and allow laboratory to industrial-scale productions (Figure 10.2).^{12,13,21} For small-scale reactions in moderately concentrated sunlight, simple laboratory-scale parabolic trough collectors have been reported. Some of these reactors were constructed from common laboratory equipment, for example, Liebig condensers and simple aluminum mirrors.^{13d} More advanced prototypes of laboratory-scale parabolic trough collectors with exchangeable mirrors and tubing, thus accommodating a larger volume of reaction mixture, have also been described.^{13c,e-f} These simple parabolic trough reactors require direct sunlight but can theoretically provide the power of 15–18 suns. However, this concentration factor is affected by imperfections in the mirrors and glass tubing, and may be lower than calculated. For industrial-scale reactions, the PROPHIS loop (modified from the SOLARIS loop, previously located at the Plataforma Solar de Almeria, PSA^{12a}) may be used, through which 35–120 L of reaction mixture may be passed. This reactor represents a line-focusing parabolic trough design, with four troughs of 8 m²

FIGURE 10.2 (See color insert.) Parabolic trough reactor for laboratory-scale experiments and the PROPHIS loop at the DLR in Cologne.

FIGURE 10.3 (See color insert.) Compound parabolic collector.

each, equipped with sun tracking systems. The concentrating power is 30–32 suns; however, it is reliant on direct sunlight and cannot be operated in diffuse conditions.²³

10.4.3 Compound Parabolic Trough Reactors

Compound parabolic trough reactors are a cross between a parabolic trough collector and a non-concentrating reactor, and are capable of utilizing both direct and diffuse sunlight (Figure 10.3).²¹ The reflective surface is in an involute shape around a cylindrical tube with a large diameter. As the diameter of the tube is so similar to that of the reflective surface, the concentration factor is considered to be the equivalent of a single sun.

10.4.4 Highly Concentrating Reactors

The use of highly concentrated sunlight for photochemical transformations has been investigated using solar furnaces. The solar furnace at the German Aerospace Centre uses a flat 52 m² heliostat and a concentrator composed of 147 spherical mirror facets to focus a highly concentrated beam of sunlight into the laboratory building.²⁴ Other solar furnaces are located in Golden, Colorado²⁵ and Odeillo, France.²⁶ Concentrations of 5,000–20,000 suns may be achieved using these furnaces. The use of highly concentrated sunlight can give higher yields in a shorter amount of time when compared to moderately concentrated light. However, the high costs for installation and the difficult operation of these systems offset the advantages of the high concentration factor.

10.5 Recent Solar Chemical Reactions

Solar applications have become widespread in recent years, within energy production, hydrogen production, and even wastewater treatment.²⁷ The area of solar chemistry research has also expanded, with investigations into syntheses using both concentrated and non-concentrated sunlight. In particular, the use of new technology has revolutionized solar chemical production, and some studies have suggested that solar plants are viable for industrial-scale production. The solar spectrum provides light in the usable range of 300–700 nm. Therefore, the reactions that may be carried out under solar conditions are limited to those that require light from this region of the spectrum.

10.5.1 Reactions Using Moderately Concentrated Sunlight

Many groups carry out their research using moderately concentrated sunlight, using both small-scale and large-scale apparatus. Campaigns by Scharf at the PSA (SOLARIS) and DLR (PROPHIS) looked at the production of fine chemicals using sunlight.¹² Three reaction types were chosen, based on the

SCHEME 10.3 [2 + 2]-cycloaddition investigated by Scharf.

wavelength of light needed, namely, the Paternò–Büchi reaction (about 400 nm), [2 + 2]-cycloadditions (acetone sensitized, below 330 nm), and dye-sensitized photooxygenations (using rose bengal, 550 nm). These reactions were carried out on the multigram scale (21–45 mol in 30–35 L). This study demonstrated that the [2 + 2]-cycloaddition reaction was feasible under solar conditions, despite the fact that only ca. 4.5% of light from the solar spectrum is ultraviolet (Scheme 10.3).

Heller et al. have reported the synthesis of pyridines via [2 + 2 + 2]-cycloaddition using a cobalt (I) catalyst and concentrated solar light.²⁸ Several studies were conducted, investigating variation of starting material and reaction solvents. Syntheses in aqueous media and emulsions of water-toluene have proven successful. Using the PROPHIS plant, 2-phenylpyridine was obtained in yields of up to 40% after solar exposure for approximately 4.5–5.5 h (Scheme 10.4).

Oelgemöller et al. have investigated the synthesis of fine chemicals, via photo-Friedel–Crafts acylations and photooxygenations, using the solar facilities at the DLR.^{12,29} The photoacylation of 1,4-naphthoquinone with butyraldehyde (Scheme 10.5) was performed on a 500 g (3.2 mol) scale in the PROPHIS loop using three troughs (24 m²). Although the reaction was run for 3 days, examination of the amount of photons collected showed that almost full conversion was achieved on the first day of irradiation. A final yield of 90% was determined using gas chromatography (GC).

Photooxygenation reactions, namely, ene reaction of citronellol (a photochemical key step in the synthesis of rose oxide, Scheme 10.6a) and [4 + 2]-cycloaddition of 1,5-dihydroxynaphthalene (Scheme 10.6b), were also investigated.¹³ Photooxygenation of citronellol was carried out on large scale, using one (32 mol in 40 L) or four (44 mol in 72 L) of the PROPHIS troughs. Complete conversions were achieved within 3 h of illumination. Likewise, photooxygenation of 1,5-dihydroxynaphthalene to juglone was carried out using smaller parabolic trough collectors (1–2 g in 200–250 mL of solvent). Yields of up to 79% were obtained.

Jung and coworkers have summarized the reactions carried out in the PROPHIS loop at the DLR, outlining synthesis of pyridines, photooxygenations, photo-Friedel–Crafts acylations, as well as *trans-cis* isomerization of stilbene.²³

An interesting study by Dincalp reports the synthesis of rose oxide from citronellol using singlet sensitizers to generate the superoxide anion radical via an electron transfer cascade (rather than the

SCHEME 10.5 Photo-Friedel–Crafts acylation of 1,4-naphthoquinone.

SCHEMES 10.6 Photooxygenation reaction of (a) citronellol and (b) 1,5-dihydroxynaphthalene.

SCHEME 10.7 Synthesis of cyclohexanone oxime and subsequent formation of ϵ -caprolactam.

commonly encountered singlet oxygen method).³⁰ This was achieved on a scale of 0.02 mol of starting material in 100 mL acetonitrile, using a fix-focus (FF) 3.5 concentrator, which gives a concentration factor of 90–100 suns. Rose oxide was formed in over 82% yield after just 2 h of illumination. In a related study, α -terpinene was converted mainly into *p*-cymene and ascaridole.³¹

Further reactions using solar concentrators were reported by Cermenati (catalytic reaction using TiO_2) using a parabolic mirror reactor,³² and Icli (dehydrogenation of abietic acid from both pure acid and pine resin) using a satellite dish of 1 m diameter.³³

Funken et al. have evaluated the economic viability of solar synthesis of cyclohexanone oxime as an industrial process, which is used in the synthesis of ϵ -caprolactam (Scheme 10.7).³⁴ Modeling of a solar industrial plant indicates that energy savings may be achieved on the light source and cooling, as well as reduced carbon dioxide emissions compared to a plant using artificial light sources.

Similarly, Monnerie has reported an economic evaluation of solar synthesis of rose oxide via a photochemical key step, comparing the use of parabolic trough reactors to synthesis using artificial light sources.³⁵

10.5.2 Synthesis in Low- to Non-Concentrating Reactors

To date, CPC reactors have primarily been used for water treatment.²¹ A synthetic study using a CPC reactor was reported by Caronna, in which thiohelicenes with 5, 7, 9, or 11 rings were synthesized by photo-induced cyclodehydrogenation of the corresponding 1,2-diheteroarylethylenes (Scheme 10.8).³⁶ In comparison with artificial light sources, the solar study gave the same yield in shorter irradiation times.

Another synthetic study was carried out by Oelgemöller et al. at the DLR in Cologne, where the photo-Friedel–Crafts reaction of 1,4-benzoquinone was investigated (Scheme 10.9).^{12a,29b} The reaction was used as a model reaction for comparison of reactors (non-concentrated, concentrated, and PROPHIS), which demonstrated that the use of a non-concentrating reactor gave superior results to those achieved in

SCHEME 10.8 Synthesis of 7-membered thiohelicene via photo-induced cyclodehydrogenation.

SCHEME 10.9 Photo-Friedel-Crafts acylation of 1,4-benzoquinone.

the PROPHIS loop under cloudy and partially cloudy conditions. The CPC reactor was shown to give greater conversion and product yield under diffuse conditions.

In a similar study, the photooxygenation of (–)-citronellol was used in a reactor comparison study.^{12f} Once again, the CPC reactor was found to give the best performance in diffuse conditions.

Covell has reported the [2 + 2]-cycloaddition of styrene to 2-acetoxy-1,4-naphthoquinones (Scheme 10.10) on a 10 g scale in a small-scale CPC reactor (concentration factor of 2).³⁷ A conversion of >96% was achieved after just 6 h exposure. In addition, the cycloadduct was isolated in high purity by simple evaporation. The by-products from irradiations with artificial light could not be detected in the crude product. Thus, solar photochemistry allowed for a minimum workup procedure.

Solar-driven alkylations have been reported by Fagnoni and coworkers using disodium benzophenondisulfonate (BPSS) as a photocatalyst.³⁸ Isopropanol and 1,3-dioxolane could be successfully added to electrophilic alkenes and alkynes in the SOLFIN facility at the PSA (concentration factor of ~4). As an example, the reaction of isopropanol with maleic acid furnished terebic acid in an isolated yield of 75% after 14 h of solar exposure (Scheme 10.11).

SCHEME 10.10 [2 + 2]-cycloaddition of styrene to 2-acetoxy-1,4-naphthoquinone.

SCHEME 10.11 BPSS-catalyzed addition of isopropanol to maleic acid.

SCHEME 10.12 Photo-induced cyclization of 1,1-dicarbonitrile.

SCHEME 10.13 Rose bengal-sensitized *trans-cis*-isomerization.

SCHEME 10.14 Photooxygenation of furfural.

The use of a flatbed reactor was reported by Heinemann for the photo-induced cyclization of 1,1-dicarbonitrile using 1,4-dicyano-2,3,5,6-tetramethylbenzene (DCTMB) as an electron acceptor (Scheme 10.12).³⁹ Comparison with concentrating reactors show that application of a flatbed reactor gives superior results under partially sunny or cloudy conditions.

A recent report by Liu looked at the isomerization of 7-*trans*-isomers of vitamin A to the more hindered *cis*-isomer, using rose bengal as a sensitizer (Scheme 10.13).^{22,40} The use of natural water reservoirs as heat sinks for photochemical reactions was demonstrated using a photochemical reactor incorporated into the body of a surfboard or boggie board. Using this reactor, complete conversion was achieved after just 15 min in May sunlight in Hawaii.

Many reactions carried out in non-concentrated sunlight still follow the “flask-in-the-sun” approach.^{41,42}

10.5.3 Reactions Using Highly Concentrated Sunlight

Although the solar furnace is primarily used for thermal applications, such as the synthesis of fullerenes (C₆₀ and C₇₀) through vaporization of graphite,^{25,26,43} there have been some reports of photochemical transformations using this technology.

The synthesis of fine chemicals has been the subject of some studies, such as the solar furnace campaign investigating photooxygenations, [2 + 2]-cycloadditions, and the Paternò-Büchi reaction.^{12b} This demonstrated the feasibility of the use of highly concentrated sunlight for synthesis of fine chemicals, such as 5-hydroxyfuranone (Scheme 10.14).

Further success in the synthesis of fine chemicals in highly concentrated sunlight was reported by Funken, who synthesized ϵ -caprolactam in yields up to 83.5%.^{34c}

10.6 Concluding Remarks

Within the area of green chemistry, photochemistry has gone “back to its roots” (and consequently “the roofs”) and has reemerged as a successful research discipline. Non-concentrated, direct sunlight is still commonly used to activate solar chemical transformations. With the help of modern solar reactor systems, however, acceleration and scale-up has been achieved. Using this technology, a series of large-scale

syntheses of industrially relevant chemicals has been realized using concentrated and non-concentrated sunlight. The energy demand for operating artificial lamps could be completely annihilated by using natural sunlight as a free and environmental light source. Environmental performance and economical evaluations have additionally shown that solar chemical processes can compete or outperform thermal and lamp-driven processes.^{9,35} This, together with the mild conditions and easy reaction control, may make solar photochemistry the *ultimate green chemistry*.

11.1 Introduction

In this review, we will give a brief overview of recent (year 2000 or later) examples of the photochemical reactions in alternative media. The word “alternative” is rather ambiguous, but we herein deal with any photochemistry that is conducted in organized, but dimensionally not well-defined, media. The photochemistry in well-organized media, such as supramolecular hosts and crystals, will be reviewed in other chapters. The less organized “alternative” media include supercritical fluids, voids in polymer and related films, ionic liquids, liquid crystals, organogels, microemulsions, micelles, vesicles, and passive voids in dendrimers and so on, which have been extensively exploited as unique media for photophysical and photochemical studies.¹ We will focus mostly on the photochemistry in such alternative media with only occasional reference to the photophysics. Because of the diversity and vagueness of the topics, the chapter will not be comprehensive; rather, we will discuss the current status and characteristics of photochemistry in alternative media by illustrating representative examples.

11.2 Photochemistry in Supercritical Fluids

11.2.1 Supercritical CO₂

Dynamically fluctuating supercritical fluids are of special interest for conducting (photo)reactions that are controlled by the diffusion rate of the reactant or intermediate. In particular, supercritical carbon dioxide is desirable not only as a “green” medium but also as a supercritical medium attainable under a relatively mild condition (the critical point at 31°C and 7.38 MPa). It was repeatedly shown that regio- and stereochemical fates of (photo)chemical reactions can be manipulated by changing the medium property,

such as density and dielectric constant, which is readily achieved in supercritical media through alteration of pressure and/or temperature in a narrow range. Supercritical fluids have lower viscosity and higher diffusivity than conventional solvents, and these properties enable reactions to proceed beyond the mass transport limitations often found in traditional multiphase systems. From the practical point of view, the easier retrieval of products simply by reducing the pressure is another clear advantage in synthetic (photo) chemistry. Accordingly, the photochemistry in supercritical fluids has been extensively studied and has been recently reviewed²; these (relatively classical) examples will not be repeated in this review.

Since carbon dioxide is totally nonflammable and nontoxic, supercritical CO₂ (scCO₂) is one of the best solvents for potentially hazardous oxidation and oxygenation processes. Gaseous oxygen is highly soluble in scCO₂, where ¹O₂ is readily generated and lasts longer (5.1 ms at 14.7 MPa and 41°C), although the lifetime is slightly dependent on the density of scCO₂.³ Consequently, 5,10,15,20-tetrakis(pentafluorophenyl) porphyrin (**1**) has been used as a photosensitizer in scCO₂. Perfluorination endows the photosensitizer with reasonable solubility in scCO₂ under high pressure. Thus, the efficient singlet oxygenations of α -terpinene (**2**) to ascaridole (**3**) and of 2,3-dimethylbut-2-ene to 3-hydroperoxy-2,3-dimethyl-1-butene were reported to occur in scCO₂. These oxygenation processes have been demonstrated to efficiently proceed in a continuous flow system using a tubular sapphire reactor to afford ca. 1 mL of product in 10 min.⁴

The photoinduced addition of aldehydes to α,β -unsaturated quinones (**4**) and enones (**5**) is an effective method for synthesizing 2-acyl-1,4-hydroquinones (**6**) and 1,4-diketones (**7**). These reactions were also performed in scCO₂, instead of benzene. The yields were improved at higher CO₂ pressures or with the addition of 5% *t*-butyl alcohol as cosolvent under the supercritical conditions.⁵

The photolysis of anthracene (**8**) in the presence of appropriate electron and hydrogen donors in scCO_2 was reported to give 9,10-dihydro-9-anthracenecarboxylic acid (**9**) in good yields, which is in sharp contrast to the result in the conventional nonpolar aprotic solvents. In this system, scCO_2 acts as both reactant and reaction medium. The reaction involves the photo-induced electron transfer from *N,N*-dimethylaniline to anthracene to form a radical anion intermediate, which was trapped by carbon dioxide to produce the reduced aromatic carboxylic acid.⁶

A photoexcitation of 2,4,6-trimethylbenzoyldiphenylphosphine oxide (**10**) in the presence of methyl methacrylate (**13**) was reported to induce free radical polymerization. The rates of propagation in supercritical and liquid CO_2 , which were determined by the time-resolved electron paramagnetic resonance studies, were comparable to each other. The rates in much viscous liquid CO_2 were slower than the diffusion-controlled ones and comparable to those in conventional solvents.⁷

The photochemistry of uranyl(VI) tributylphosphate complex in scCO_2 was also studied. The result was interpreted as the uranyl(VI) complex was reduced to uranium(V) by photoexcitation in the presence of ethanol, which was followed by the disproportionation to give the uranium(IV).⁸ The photocatalytic oxidation of 1-octanol on silanized TiO_2 suspended in aerated scCO_2 was also investigated at a various temperatures and pressures. The maximal photocatalytic production was observed at the CO_2 pressure of 10 MPa. These experimental results were explained by differences in mass transfer efficiency of the reactants and products formed on partially desilanzed TiO_2 powder in scCO_2 .⁹

Enantiodifferentiating photoaddition of methanol to 1,1-diphenylpropene (**16**) has been extensively studied using the chiral 1,4-naphthalenedicarboxylate (**17**) as the sensitizer. The enantiomeric excess (ee) of photoadduct (**18**) obtained in the reaction was critically affected by applied pressure and/or temperature. The product's ee was enhanced by increasing alcohol size and pressure, thus affording a best ee of 43% for the photoaddition of 2-propanol in scCO_2 at 18 MPa.¹⁰ However, the dependence of ee was discontinuous at the critical density, accompanying a big jump caused most probably by enhanced clustering of the alcohol. Interestingly, such sudden leap in the ee near the critical CO_2 density was observed at any given temperature, but at different pressures.¹¹ The differential activation volumes, $|\Delta\Delta V_{\text{R-S}}^\ddagger|$, obtained for the supercritical and particularly the subcritical regions, were

much larger than those obtained with the same photoreaction in conventional solvents, indicating the more selective solvation to one of the diastereomeric exciplexes particularly in the subcritical region. The $\Delta\Delta V_{R-S}^\ddagger$ values obtained at the near-critical region (9–10 MPa) were anomalously large, which was attributed to the dynamic nature of $scCO_2$ in the subcritical region, as independently demonstrated physicochemically by the density fluctuation studies. These explanations were also supported by the fluorescence studies.¹²

The photolysis of 5,5-diphenyl-4-penten-1-ol (**19**) in the presence of the same chiral sensitizer (**17**) was performed in $scCO_2$ to give the intramolecular cyclization product (**20**) in good to modest yields. The ee of product (**20**) was again highly pressure dependent, displaying a dramatic leap from nearly 0 in near-critical CO_2 (8–10 MPa) to the maximum value of 29% in purely $scCO_2$ at 12 MPa. More surprisingly, it was revealed that the dramatic increase of the ee of photoproduct is achieved by simply adding an entrainer such as diethyl ether to $scCO_2$, although the detailed mechanism was not fully elucidated.¹³

As another example of the unimolecular reactions, the sensitized enantiodifferentiating photoisomerization of (*Z*)-cyclooctene (**21**) to (*R*)- or (*S*)-(*E*)-cyclooctene (**23**) with chiral benzenepolycarboxylates (such as **22**) was studied in $scCO_2$. A similar jump of the product's enantioselectivity in the near-critical region (8–10 MPa of CO_2) was also observed in this system.¹⁴

11.2.2 Supercritical Rare Gases

The photolysis of iron pentacarbonyl, $\text{Fe}(\text{CO})_5$ (**24**), has been widely investigated as a representative compound in organometallic photochemistry, using various techniques such as matrix isolation, flash photolysis, time-resolved infrared spectroscopy, and electron diffraction. Consequently, the addition reactions of the triplet fragments $^3\text{Fe}(\text{CO})_4$ and $^3\text{Fe}(\text{CO})_3$ (**25–27**) formed upon photolysis of $\text{Fe}(\text{CO})_5$ (**24**) in supercritical rare gases (xenon and argon) have been investigated in detail.¹⁵ The photobehavior was compared with that in supercritical methane, as well as in conventional solvents. A theoretical study on these systems revealed that these spin-forbidden reactions are caused by the spin crossover followed by ligand addition via the nonadiabatic transition state.¹⁶ The photochemistry of related molybdenum species, *trans*- $[\text{CpMo}(\text{CO})_3]_2$ ($\text{Cp} = \eta^5\text{-C}_5\text{H}_5$), in scCO_2 has been also studied by the time-resolved infrared spectroscopy.¹⁷

The photolysis of asymmetrically substituted diazene (**29**) in supercritical xenon and CO_2 and compressed krypton was investigated by nanosecond laser flash photolysis.¹⁸ The cage effects on the radical intermediates (**30** and **31**) in different fluids (supercritical CO_2 , Xe, and Kr) were examined to disclose the absence of the critical clustering or so-called enhanced cage effect under the near-critical conditions.

11.2.3 Supercritical Methane, Ethane, and Other Hydrocarbons

Photoreaction of a homogeneous mixture of ethane, carbon monoxide, and rhodium catalyst, $[\text{Rh}(\text{CO})(\text{PMe}_3)_2\text{Cl}]$ (**33**), was reported, and the formation of propionaldehyde was confirmed by mass spectrometry. During the course of photolysis, the catalyst was decomposed to $[\text{Rh}(\text{CO})_2(\text{PMe}_3)\text{Cl}]$ (**34**), and this species was shown to be responsible for the carbonylation of ethane. The photochemical carbonylation of ethane and other hydrocarbons by rhodium catalysts was also reported in scCO_2 . The similar carbonylation of methane did not proceed in supercritical methane.¹⁹

Upon laser irradiation of near-critical benzene at 266 nm, carbon anions were produced in both subcritical (200°C) and supercritical (290°C) benzene, whereas carbon coils were obtained on an alloy catalyst composed of Fe, Cr, and Ni in supercritical benzene. The use of supercritical fluids for preparation of structured carbons is attractive, since the method requires much lower temperature than that used in conventional methods.²⁰

11.3 Photochemistry in Polymer and Related Films

11.3.1 Polyethylene and Polypropylene Films

A number of investigations demonstrate that the cavities in polyethylene (PE) films can be subtly “tuned” by temperature and the induced microscopic changes in polymer structure and morphology are valuable for altering or tuning the reactivity and selectivity of a wide variety of photoreactions. The passive voids of PE cavities can be easily modulated by their degree of crystallinities and by unidirectionally stretching the films. The voids can also be templated by incorporating some guest molecules and the template shape is retained for some time even after the removal of the guest template. As such, the passive PE cavities are positively employed for controlling the photochemical reactions, as shown in the following examples.

The selectivity of photo-Fries rearrangements has been widely investigated in isotropic solutions. Accordingly, the photolysis of 1-naphthyl and 2-naphthyl acylates (37 and 43) was conducted in unstretched and stretched PE films of different crystallinities and the results were compared with those obtained in isotropic solutions.²¹ The influence of variables such as size and position of the aryl groups of the esters, degree of crystallinity, free volume, and unstretched/stretched state of the films has been explored. The void’s free volumes were much smaller than the van der Waals volumes of the naphthyl molecules under investigation and the naphthyl esters inside PE cavities acted as templates for the formation of photoproducts. Stretching of the film enhanced the templating effect and strengthened the van der Waals attractions with cavity walls in the case of naphthyl myristates, thus inducing an increase in reaction selectivities in PE films. There was, on the contrary, no direct correlation between the void’s free volume of PE films and the selectivity of photoreactions.

Photo-Fries rearrangements of phenyl phenylacrylates (**49**) were investigated in isotropic solutions and in PE films and the results were compared with those obtained for the corresponding naphthyl esters. Unlike the naphthyl esters, the product distribution and the rate of radical recombination were much less sensitive to film stretching or the type of PE employed in the case of phenyl esters. Photoirradiation of 5,6,7,8-tetrahydro-1-naphthyl phenylacetate, which is comparable in size to 1-naphthyl phenylacrylates, but electronically equivalent to phenyl phenylacrylates, revealed that the electronic properties of the two aryloxy radicals are principally responsible for the differences in the overall rates of recombinations of the intermediate radical pairs.²²

Recombination of prochiral radical pairs derived photochemically from 1-naphthyl (*R*)-2-phenylpropanoate (**58**) in PE films was reported to occur with significant enantioselectivities due to the confining effect in PE cavities. The regioselectivities of photo-Fries (**59** and **60**) and of decarbonylation products (**61**–**63**) obtained upon photolysis of this chiral ester were very different from each other, and the enantioselectivities of the decarbonylation products were heavily dependent on the properties of the PE cavities, such as wall stiffness and mean free volumes.²³

The photochemistry of 1-(4-methylphenyl)-3-phenyl-2-propanone (**64**) has been investigated in PE films of varying crystallinities at different temperatures.²⁴ The recombination selectivity of the triplet pairs of benzylic radicals derived from the photolysis of ketone **64** has been used as a tool for assessing the nature of the PE cavities and its influence on the motion of the radicals. It was shown that the in-cage recombination is favored at low temperatures and in PE of high crystallinities. These results were interpreted from the structural point of view, by considering the shape, free volume, wall stiffness, and permeability of the reaction cavities, and also from the dynamic point of view, by taking into account of the kinetic competition of the in-cage combination versus cage escape of the radical pairs. Recent examinations by the steady-state and laser-pulse irradiations of dibenzyl ketone derivatives with *p*-methyl or *p*-hexadecyl chain in PE films with 0%, 46%, and 68% crystallinities revealed that the separate components of reaction, affected by the (in-cage) “cage effect” as well as the (out-of-cage) “persistent radical effect,” are both responsible for the formation and relative contributions of decarbonylated products (**65–67**).²⁵

Photo-Claisen rearrangement of benzyl phenyl and benzyl 1-naphthyl ethers (**68**) has been also examined in PE films of different crystallinities. The ratios of the principal rearrangement products, benzyl arylol positional isomers (**69–71**), indicated that the reaction is less selective in the PE films than in the zeolite cavities. The results were explained in terms of the passive walls of the PE cages and the limited free volume of cavities.²⁶

The radical pairs produced directly from the lysis of the first excited singlet state of enantiomerically pure 1-naphthyl (*R*)-1-phenylethyl ether (**73**), or indirectly from the decarbonylation of the aryl radical formed in the photo-Fries reaction of 1-naphthyl (*R*)-2-phenylpropanoate (**58**), have been shown to (partially) lose their stereochemistry in the PE films, which is in contrast to the photo-Fries rearrangement in PE films, where the stereochemistry is fully preserved.²⁷ Quite interestingly, these results are better interpreted by assuming that the PE cavities are templated by the guest molecules and the templated shapes are retained to some degree for a period required for decarbonylation. Comparison of the fates of the directly and indirectly formed radical pairs has been employed as a tool for elucidating the nature of the reaction cavities in the polyethylene films and how the combination of the radical pairs is influenced by the initial location within a cavity.

The photodecarboxylation of 2,4,6-trimethylphenyl (*S*)-2-methylbutanoate (**75**) in unstretched high-density polyethylene (HDPE) films afforded (*S*)-1-(2-methylpropyl)-2,4,6-trimethylbenzene (**76**) as the sole detectable product.²⁸ In other PE films, organic solvents, and cyclodextrin cavities, the cage-escaped products derived from the Fries-type bond scission were concomitantly obtained, but the decarboxylation product was obtained with stereoretention without exception, indicating that the decarboxylation is a completely concerted process.²⁹ A recent investigation on the photoreaction of *o*-cresyl acylates in PE films confirms that the importance of the shape of substrate and thus the ability to interact with their environment to the stereoselectivity of the photochemical outcomes.³⁰ These results reveal the importance of the media in controlling the conformation and photoreaction of aryl esters.

11.3.2 Poly(Vinyl Acetate) Films

The photo-Fries and associated photoreactions of 1-naphthyl acylates (**37**) have been also examined in two types of poly(vinyl acetate) or PVA films above and below their glass transition temperatures.³¹ Comparison of the results in PVA films with those in low-viscosity solvents (ethyl acetate and hexane) and low-polarity polymer films (PE and polypropylene) indicated that interactions of the radicals produced in the photolysis of esters with the acetate pendant groups of PVA films, as well as the mode of PVA's chain motions, enormously influence the course of the photo-Fries rearrangements. The distributions of photo-Fries products were reasonably explained by the initial conformation of the guest molecules accommodated in the film cavities.

11.3.3 Nafion Membranes

Methanol-swollen Nafion beads also provide the microenvironment for controlling photochemical reaction pathways. Thus, the product selectivities have been examined in photo-Fries rearrangement of naphthyl esters, Norrish Type I reaction of 1-phenyl-3-*p*-tolyl-propanone, Norrish Type I and Type II reactions of benzoin alkyl ethers, and photodimerization of acenaphthylene and *N*-benzyl maleimide.³² For example, the photoirradiation of naphthyl benzoate (**37**) in Na⁺, Tl⁺, and Cs⁺ ion exchanged Nafion beads affords single product (2-benzoyl-1-naphthol, **38**), while a pair of rearranged products as well as the cage-escaped products are concomitantly formed in isotropic solvents such as hexane, methanol, and benzene.

The ion-exchanged Nafion interior was also used to investigate the influence of chiral auxiliaries in photochemical reactions. Thus, the asymmetric photoisomerization of *trans,trans*-2,3-diphenylcyclopropane-1-carboxylic acids, electrocyclization of 2-oxo-1,2-dihydropyridine acetic acids, and oxa-di- π -methane rearrangement of 1,2-dihydronaphthalenones have been reported. For example, irradiation of pyridone derivative **77** in Na⁺ or Li⁺ Nafion yielded the bicyclic products (**78** and **79**) in 13%–21% diastereomeric excess (de), whereas the same reaction in solution afforded only 0%–4% de.³³

Water- and methanol-swollen Nafion membranes were used as the microenvironment to effectively control the photochemical reaction pathway of stilbazole derivatives (**80**). Azaphenanthrene (**82**) was obtained in high yield upon irradiation of **80** in the membrane, while only the cyclodimerization products (**83** and **84**) were formed in homogeneous solutions.³⁴

11.4 Photochemistry in Ionic Liquids

The photochemistry in ionic liquids (ILs) has been extensively studied and thus repeatedly reviewed.³⁵ Therefore, we deal with only the recent development and will not refer to the work cited in the chapter “Photochemistry in Ionic Liquids” of the previous edition of this book.³⁶ The photochemistry of ILs that contain photoreactive groups will also be disregarded, and we will focus on the systems that use ILs as reaction media for photochemical reactions. Typical room-temperature ILs, such as 1-butyl-3-methylimidazolium tetrafluoroborate (bmim-BF₄) and hexafluorophosphate (bmim-PF₆), are most frequently employed as the media for photoreactions, but the ILs that contain weakly coordinating bis(trifluoromethanesulfonyl)amide moiety, such as 1-butyl- and 1-ethyl-3-methylimidazolium bis(trifluoromethanesulfonyl)amides (bmim-NTf₂ and emim-NTf₂), are also used. The photoreactions can be conducted also in the microemulsions formed by mixing IL with organic solvent and/or aqueous solution. In this section, we will outline the recent examples of photoreactions performed in ILs and in the microemulsions using ILs.

The IL bmim-PF₆ has been employed as a solvent for a series of representative photochemical reactions involving energy transfer, hydrogen transfer, and electron transfer.³⁷ ILs show unique characteristics such as low oxygen solubility, slow molecular diffusion, elongation of triplet excited state and radical ion lifetimes, and weakening of the donor–acceptor (or charge transfer) interactions. The photoinduced electron transfer of anthraquinone³⁸ and duroquinone³⁹ in mixed binary solutions of IL (bmim-PF₆ or bmim-BF₄) and organic solvent has been studied by laser flash photolysis. The absorption of the triplet excited state of the quinone was blueshifted in the IL–acetonitrile mixtures, and the triplet excited state of the quinone abstracted hydrogen from the IL. In a binary mixture of IL and acetonitrile, the rate of electron transfer depended primarily on the concentration of IL at lower fractions of IL. In contrast, at higher fractions of IL, the network structures due to the hydrogen bond and viscosity became dominant and the decay rate constant decreased with increasing fraction of IL. A critical point was observed at a volume fraction of ~0.3 in IL. Photoinduced electron transfer from a series of electron donors to 9,10-dicyanoanthracene has been studied in bmin-PF₆ and omim-PF₆ (1-octyl-3-methylimidazolium hexafluorophosphate).⁴⁰ The fluorescence quenching occurred at rates 1–2 orders of magnitude greater than the diffusion limit. This and related theoretical studies revealed that the electron transfer between the excited 9,10-dicyanoanthracene and the donor molecule occurs in the hydrophobic, nonpolar alkyl chain region of the ILs. A detailed study of the photoinduced electron transfer between pyrene

and *N,N*-dimethylaniline was performed recently in four different room-temperature ILs (bmim-BF₄, bmim-PF₆, bmim-NTf₂, and emim-NTf₂), by using the steady-state and time-resolved fluorescence and laser flash photolysis techniques.⁴¹ Because of the slow diffusion in ILs, quenching occurs at a slower rate in ILs than in conventional organic solvents. In sharp contrast to the well-established observation of exciplex fluorescence in conventional media, no exciplex emission was observed in ILs. However, the quenching rate constant, much larger than the diffusion-controlled rate, was explained by the microenvironmental viscosity around the electron donor and acceptor, which is different from the bulk viscosity of the IL. Furthermore, the solvent-mediated electron transfer in a pyridinium IL, *N*-butylpyridinium bis(trifluoromethanesulfonyl)amide, was reported recently.⁴² The electron transfer between Ru(bpy)₃²⁺ complex and methyl viologen, coupled with the reduction of the carbonyl group in ILs, was reported.⁴³ Intramolecular electron transfer was also studied in IL, and the photolysis of 4-(*N*-pyrrolidino)naphthalene-1,8-imide-pyromellitimide was examined in emim-NTf₂.⁴⁴

The photoisomerization of 3,30-diethyloxadecarboxyanine iodide was investigated in bmim-PF₆ and in a binary mixture of the IL and water, by using the steady-state and time-resolved fluorescence spectroscopy. The photoisomerization rate was dramatically retarded in the IL, compared to that in an isotropic solvent of comparable polarity. The activation energy for photoisomerization was also determined in various media.⁴⁵ Photoisomerizations of 4'-hydroxyflavylium⁴⁶ and 4',7-dihydroxyflavylium⁴⁷ were studied in bmim-PF₆, and their multistate, multifunctional switching properties in a biphasic IL-water mixture were shown to be quite valuable. The photochromic properties of *N*-methyl nitrobenzospiropyran-merocyanine system (**85** and **86**) were studied in ILs containing bis(trifluoromethanesulfonyl)amide anion, and the kinetics and thermodynamics of the process were shown to be sensitive to the nature of the cation.⁴⁸ Recently, a variety of ILs containing carboxylate anions were prepared and *N*-substituted photochromic spiropyran derivatives were employed to determine the polarities of these protic or fluorine-containing ILs.⁴⁹

The formation of ¹O₂ was suggested upon photoirradiation of indigo carmine in bmim-BF₄, and the quantum yield of ¹O₂ production was estimated to be 0.53.⁵⁰ The oxidation of thioanisole photosensitized by methylene blue has recently been studied in a series of anhydrous imidazolium- and pyrrolidinium-containing ILs.⁵¹ It was shown that the ILs can be used as convenient solvents for oxidation of thioanisole, although thioanisole is practically unreactive in conventional aprotic solvents. Upon oxidation of thioanisole by ¹O₂, a small amount of the corresponding sulfone was formed in pyrrolidinium-based ILs, but the sulfoxide was exclusively produced in imidazolium-based ILs. This was explained as the persulfoxide is converted to a hydroperoxysulfonium ylide intermediate in pyrrolidinium-type ILs (as it occurs in conventional aprotic solvents), while in imidazolium-type ILs hydrogen-bonded persulfoxide is probably formed. The photochemical oxidation of alcohols with molecular oxygen was efficiently performed in high conversion and selectivity in several ILs by using 12-tungstophosphoric acid immobilized in mesoporous MCM-41.⁵²

Millimeter-long nanowires of charge transfer silver tetracyanoquinodimethane materials were prepared by the photochemical reduction of tetracyanoquinodimethane in bmim-BF₄ containing benzyl alcohol as a sacrificial electron donor. The nanowires were also prepared in this IL by using the oxidation of water as a counterreaction (at a slower rate), indicating that the ILs may provide a favorable environment for photochemical water splitting. It is to note that the adventitious water as impurity may have affected the photochemical behavior in ILs.⁵³

Intra- and intermolecular copper(I)-catalyzed [2 + 2] photocycloaddition reactions of nonconjugated alkenes were recently achieved efficiently in an ammonium salt-based room-temperature ILs such as

trimethyl(butyl)ammonium bis(trifluoromethylsulfonyl)imide (tmba-NTf₂). The IL, tmba-NTf₂, is transparent at the irradiation wavelengths and was quite stable under the irradiation conditions, and was easily recovered and recycled. In contrast, no cycloadduct could be isolated when the same reaction was carried out under the identical irradiation conditions in bmim-NTf₂, which absorbs the UV light to suffer extensive photodecomposition.⁵⁴ Intramolecular photocycloaddition of 1,6-diene (**87**) smoothly proceeded in bmim-NTf₂ in yields comparable to those obtained in diethyl ether. Intermolecular [2 + 2] photocycloaddition in tmba-NTf₂ was found to proceed in an even better yield than in conventional organic solvents. Thus, the photoirradiation of bicyclopentadiene and norbornene in IL produced the corresponding dimers in 71% and 90% yield, respectively. The irradiation of cyclopentene derivative (**89**) under the same conditions gave a 8:1 mixture of head-to-tail *cis-anti-cis* cycloadduct (**90**) and its diastereomer in 56% combined yield.

Arenediazonium tetrafluoroborate salts (**91**) underwent the nucleophilic substitution followed by the dediazonium upon photolysis in bmin-NTf₂ to predominantly give the oxy anion quenching products (**92**) in good yields, together with small amounts of Schiemann reaction product (**93**) and bis(trifluoromethylsulfonyl)imide (**94**).⁵⁵ Despite the nonnucleophilic and noncoordinating nature of NTf₂ anion, the nucleophilic attack occurred predominantly at the O-atom of NTf₂ anion, while the Schiemann reaction was a minor pathway in this IL. On the contrary, the Schiemann reaction of imidazole derivatives (**95**) was reported to occur efficiently in bmim-BF₄. The use of bmim-BF₄ dramatically improved the yield of the fluorodediazonium product (**97**). Careful temperature control at 0°C was shown to be essential to minimize the photodecomposition of the IL.⁵⁶

The photochemistry of chiral (salen)aluminum(III) chloride complex (**98**) has been studied in imidazolium ILs (bmim-BF₄ or PF₆). The ILs particularly stabilized the (saren)Al(II) radicaloid species (**99**) generated by the homolysis of the Al–Cl bond. The half-life of this species varied depending on the solvent, indicating that the counteranion of IL played an important role by changing the IL's polarity and viscosity to affect the lifetimes of the singlet excited state of pentacoordinated salen Al(III) and of the Al(II) radicaloid intermediate.⁵⁷

The 1-methylimidazole-containing triplet photosensitizers (**103** and **104**) were designed and synthesized in order to enhance the solubility in room-temperature ILs. The photosensitized isomerization of *trans*- to *cis*- β -ionol (**101** and **102**) was efficiently carried out in bmim-BF₄ and the sensitizer/IL mixture was reusable. These sensitizers remained in the IL layer when the solution was extracted with organic solvent.⁵⁸

Chiral ILs are particularly attractive in view of their potential ability of chiral recognition and discrimination, which is applicable to asymmetric synthesis and optical resolution. Recently, several chiral ILs (**107**–**110**) have been used as chiral solvents for the enantiodifferentiating photoisomerization of dibenzobicyclo[2.2.2]octatriene diacid (**105**). The enantioselectivities obtained (3%–12%), though modest in an absolute sense, are the highest values reported so far for a unimolecular photochemical reaction performed in chiral IL. The chiral induction was attributed to the ion-pairing interaction of the deprotonated diacid with the IL cation.⁵⁹

Chiral ionic liquids:

A large magnetic field effect on the photoinduced hydrogen abstraction reaction of benzophenone with thiophenol was reported in the ammonium, pyrrolidinium, and piperidinium ILs.⁶⁰ Interestingly, the effect of magnetic field was not straightforward⁶¹; the yield of escaped benzophenone ketyl radical gradually decreased by applying the magnetic field of up to 2 T, then reached a terrace at 2–10 T, and again decreased at 10–28 T to eventually afford a 25% reduced yield at 28 T, indicating the operation of more than one mechanism for the ketyl radical.

An IL–organic solvent–water ternary system, consisting of 1-tetradecyl-3-methylimidazolium bromide (tmim-Br), *p*-xylene, and water, was employed for the photodimerization of 9-substituted anthracenes (**111**). The ternary system forms hexagonal and lamellar liquid crystals as well as microemulsions. These organized media were effective in solubilizing and preorientating the anthracene derivatives with a polar 9-substituent, and thus enhanced the formation of head-to-head cycloaddimer (**112**).⁶² Fluorescence resonance energy transfer study from coumarin 480 to rhodamine was also reported in microemulsions comprised of pmim-BF₄ (1-pentyl-3-methylimidazolium tetrafluoroborate) in a mixture of TX-100 and benzene with and without added water.⁶³

Choosing the proper IL for specific photochemical reaction is encouraged, since the IL used as a solvent is frequently involved in the photoreaction. For instance, the photochemistry of IL investigated by femtosecond pump-probe absorption spectroscopy revealed that, in addition to the generation of solvated electron, di- and trihalide ions are formed upon continuous irradiation of halide-containing ILs (bmim-I or hmim-Cl).⁶⁴ It is also to note that the diffusion coefficient of diiodide anion radical in ILs becomes much larger than that in conventional organic solvents, due to the Coulomb interaction between diiodide and IL cation.⁶⁵

11.5 Photochemistry in Microemulsions, Micelles, Vesicles, and Dendrimer Voids

Reverse micelles and water-in-oil microemulsions are microscopic spherical pools of water surrounded by a monolayer of surfactant separating the water pool from the hydrophobic bulk solution. The sensitized photooxidation via the $^1\text{O}_2$ has been extensively investigated in such media. Thus, the photooxidation of glycyl-glycine sensitized by water-soluble anthraquinone derivatives was investigated in the micelles and microemulsions of sodium bis(2-ethylhexyl) sulfosuccinate.⁶⁶ The formation of semi-quinone radicals in the photosensitized oxidation of hydroquinone substrates was also studied in the reverse micelle.⁶⁷ The photooxidation of γ,δ -unsaturated ketone was investigated in microemulsion and in homogeneous solution and the results were compared. The photooxidation of homoallylic substrate **114** in acetonitrile or acetone gave tertiary hydroperoxide (**116**) and 3-hydroxy-1,2-dioxane (**117**) as the major products, while dioxane **117** and epoxide (**118**) were obtained in sodium dodecyl sulfate microemulsion, both of which were the secondary products derived from the allylic hydroperoxides (**115** and **116**)⁶⁸ Diastereoselectivity of the singlet photooxidation of mesitylol was also examined in microemulsions.⁶⁹

The photosensitized oxidation of several olefins was also investigated in mixed surfactant vesicles. In the photosensitized oxidation of (*E*)-stilbene and (*E,E*)-1,4-diphenyl-1,3-butadiene in vesicles, the corresponding 1,2-dioxetanes were formed in quantitative yields, which is in sharp contrast to the oxidation in homogeneous solution where the [4 + 2] cycloaddition product of singlet oxygen to the diene was the sole product. It is interesting to note that $^1\text{O}_2$ generated in the bilayer or the inner water pool of a vesicle is able to diffuse out and enter into the bilayer of another vesicle through the outer aqueous phase and reacts with the target molecules.⁷⁰ The singlet oxygenation of α -pinene was also investigated in vesicles.⁷¹ The selectivity of oxygenation in mixed surfactant vesicles was controlled by changing the location of the substrate and sensitizer molecules in the reaction media.⁷² The quantum yield of $^1\text{O}_2$ upon photosensitization with palladium bacteriopheophorbide, a potential reagent for vascular targeted photodynamic therapy, was almost unity in organic solvents, but only ca. 0.5 in micelles and vesicles, where superoxide and hydroxyl radicals are formed in a minimal quantum yield of 0.1%. Analysis of the photoproducts suggests that the formation of oxygen radicals involves both electron and proton transfer from the pheophorbide at the membrane/water interface to a colliding oxygen molecule, consequently forming superoxide, then hydrogen peroxide, and finally hydroxyl radicals.⁷³

The photoisomerization of (*E*)-stilbene (**119**) was studied in microemulsions composed of Triton X-100, 1-pentanol, and water in different ratios. The yield of (*Z*)-stilbene (**120**) increased with the increase of water content or with the decrease of Triton X-100 content, and the oil-in-water structure

was found most suitable for the photoisomerization.⁷⁴ (*E*)-1-(4-Methoxyphenyl)propene (anethole, **121**) was employed as a substrate in the study of photochemical behavior in microemulsions, as this substrate undergoes spontaneous emulsification without adding external surfactants.⁷⁵ Thus, the photochemical behavior of microemulsions obtained upon dilution of ethanolic solutions of anethole (**121**) with water was compared with that of homogeneous ethanolic solutions of the substrate. The photolysis of **121** afforded the (*Z*)-isomer (**122**) and cyclodimers (**123–125**), along with the oxidation and/or solvolysis products (**126–128**). Significant differences in reactivity were observed in both media, as the yields of isomerization (**122**) and dimerization (**123–125**) were considerably reduced in microemulsions. In contrast to the photoreaction in homogeneous solutions, where the (*Z*)-rich photostationary state (ca. 80%) was reached rapidly, the proportion of (*Z*)-isomer upon irradiation of anethole microemulsions remained below 15%. In the presence of oxygen, the formation of anethole oxide was observed, which further underwent polymerization in the aggregated microemulsion of anethole. The lower photoreactivity of anethole in microemulsions was interpreted in terms of the faster nonradiative decay due to faster internal conversion.

Photosensitizing surfactants (**132** and **136**) have been employed for the polar addition of indene (**129**) and 1,1-diphenylethene (**133**) in oil-in-water emulsion. These photosensitizing surfactants were shown to work more efficiently in microemulsion (in water) than in homogeneous organic solvent.⁷⁶ Although the reaction of indene in an oil-in-water emulsion proceeded efficiently to give the corresponding alcohol as a major product, the yield reported was strongly influenced by the size of oil droplet.⁷⁷

The photocycloaddition of 9-substituted anthracenes (**111**) has been investigated in water-in-oil microemulsions prepared from sodium bis(2-ethylhexyl) sulfosuccinate, dichloromethane, and water. While irradiation of the aforementioned substrates in isotropic media afforded the corresponding head-to-tail photocyclodimer (**113**) as the major product, photoirradiation in the microemulsion almost exclusively yielded the head-to-head dimer (**112**). These observations were interpreted in terms of the preorientation of the substrate molecules at the interface of the water pool in the microemulsions.⁷⁸ The reductive photodebromination of polybrominated diphenyl ethers was investigated in nonionic surfactant micelles.⁷⁹ Photoinduced electron transfer from zinc tetraphenylporphyrin was studied in nonaqueous microemulsions composed of *n*-heptane, sodium bis(2-ethylhexyl) sulfosuccinate, and ethylene glycol.⁸⁰ The thermodynamics and kinetics of photoinduced electron transfer in bacterial photosynthetic reaction centers were also investigated in micelles and vesicles formed from different phospholipids of physiological importance.⁸¹

Water-soluble poly(alkyl aryl ether) dendrimers (**137**) have been extensively explored for their use as hosts of organic substrates in aqueous media. The photo-Fries reactions of 1-naphthyl benzoate and phenyl ester as well as the α -cleavage reactions of dibenzyl ketones and benzoin alkyl ethers in voids of dendrimers have been examined.⁸² The photolysis of 1-phenyl-3-*p*-tolyl-propan-2-one and benzoin ethyl ether as well as the photodimerization of acenaphthylene was investigated in voids of different types of dendrimers.⁸³ It was demonstrated that the dendrimer can encapsulate the substrate, intermediates, and products in its voids and restricts the mobility of radical intermediates. Comparative studies of the same photoreaction in micellar media demonstrated that dendritic media offers much better constraint than the micelles.

Typical dendrimers for microenvironment: R = OH, CO₂H, CO₂Me

137

11.6 Photochemistry in Liquid Crystals and Organogels

A number of investigations have been carried out to induce the chirality into liquid crystals by means of photochemical procedures and the representative results have recently been reviewed.⁸⁴ In this chapter, we focus on the photochemistry of molecules inside the liquid crystals as media, but will not refer to the photochemistry and photophysics of the liquid crystal itself.

The charge separation and recombination processes in a carotenoid–porphyrin–fullerene triad, as a mimic of the photosynthetic reaction center, have been studied in the different phases of two uniaxial liquid crystals.⁸⁵ The effects of orientation on the electronic coupling element of the molecular triad in liquid crystal were interpreted by the simulations of the EPR spectra of the carotenoid triplet state, which can be useful in designing a better model system with an optimized charge separation efficiency.

Lyotropic liquid crystals have been used as media for the photochemical inter- and intramolecular hydrogen abstraction of cyclohexyl phenyl ketone (**138**) to afford α -cyclohexylbenzyl alcohol (**139**) and 1-phenyl-6-hepten-1-one (**140**). The efficiency of the photoreaction was much higher in the liquid crystals than in hexane solution. The ratio of intra- and intermolecular products (**140/139**) was found to be 30:1 in 1-propanol but less than 3:1 in both lamellar and hexagonal liquid crystals, showing that the intramolecular reaction is greatly hampered in the liquid crystals. Studies on the product distribution

in the absence and presence of electron donors revealed that liquid crystals not only restrict the motion of the substrate and intermediates but also keep the substrate and electron donor together during the photoreaction. A comparison with the same reaction in sodium dodecyl sulfate micelle indicated that the liquid crystal provides a better constraint for the reaction.⁸⁶ The chiral induction in **139** obtained upon irradiation with prolinol, ephedrine, and their derivatives added as chiral inductor turned out to be inefficient, affording as low as 4%–5% ee.

Photochemistry of tropolone methyl ether **141** (R = Me) has been examined in lyotropic liquid crystals in the presence of chiral inductor. Anisotropic hexagonal liquid crystals significantly induced the chirality in the photoelectrocyclization of the tropolone methyl ether better than lamellar liquid crystals. Thus, norephedrine was able to give the major product **142** (R = Me) in 40% ee, when the reaction was performed in the hexagonal liquid crystals. The photoreaction of chiral tropolone ether **141** (R = 2-methylbutyl) was also performed in the presence of an additional chiral inductor in liquid crystals. It was shown that norephedrin and prolinol are effective in the hexagonal liquid crystals, both affording **142** in 35% de.⁸⁷ The partially rigid environment of liquid crystals was considered to prevent the dissociation of the substrate–inductor complex, enhancing the stereoselectivity of the photoproducts.

The photodimerization of 2-anthracenecarboxylic acid (**144**) has been studied in the presence of the amphiphilic amino alcohol (**149**) in the liquid-crystalline medium. The photoreaction was comparatively studied in two smectic and isotropic phases. The two smectic phases were found to show acceptable reactivity to give a mixture of the corresponding dimers (**145**–**148**) in 23%–55% yield upon photoirradiation, while 87% of the starting material was consumed in the isotropic phase under the similar conditions except for the phase and temperature. These and related observations indicated that the liquid-crystalline phases are superior to the crystalline phase in view of reaction probability. Quite interestingly, the regioselectivity (head-to-head versus head-to-tail ratio) of the photodimerization changed dramatically depending on the phase, and the head-to-head dimers were obtained exclusively in both of the smectic phases, demonstrating the peculiar property of liquid crystals as constrained reaction media. The liquid-crystalline media also offer better environments for chiral induction.⁸⁸ The photodimerization of 1-anthracenecarboxylic acid (**150**) was also investigated in the liquid-crystalline medium. The reaction proceeded with an excellent regioselectivity to give the head-to-head dimers exclusively. The moderate diastereoselectivity (*anti*/*syn* ratio) of 24% was reported for the dimers **151** and **152**, but the ee of the *anti* head-to-head product **151** was quite unsatisfactory (2% ee).

The D-alanine derivative possessing a 3,4,5-tris(*n*-dodecyloxy)benzamide moiety (**153**) was found to be an efficient gelator for nonpolar solvents such as cyclohexane. The photocyclodimerization of 2-anthracenecarboxylic acid (**144**) in the gel matrix was highly stereoselective, exclusively affording the head-to-head photodimers (**147** and **148**). This is in contrast to the results in isotropic media. Unfortunately, the enantioselectivity induced by the chiral gelator was poor (10% ee).⁸⁹ The several other gelators containing a 3,4,5-tris(*n*-dodecyloxy)benzoylamide backbone have been developed and their photochemistry was explored.⁹⁰

The organogels have been also employed as media for photochromic systems, and the photochromic behavior of a variety of benzopyranindolines was studied in organogels.⁹¹ The lifetime of the colored photomerocyanine with a succinyl ester functionality was found to be increased by a factor of >300 in the organogel derived from 4-*tert*-butyl-1-phenylcyclohexanol.

11.7 Conclusions

In this concise review of the photochemistry in alternative media, we overview the recent exploration of a variety of photoreactions in the nonconventional media.

Supercritical fluids are used as media that provide much efficient diffusion of the reactant and intermediate than in the conventional organic solvents. This usually facilitates the efficiency of bimolecular

reaction, but the most striking features of the supercritical fluids are found in the near-critical region, that is, the transition region from gas phase to supercritical phase. The effect was explained by the specific clustering to the solute of medium molecules in the near-critical region. Although the usefulness of such peculiar phenomena on the control of stereo- and regioselective photoreaction is evident, the detailed mechanism remains to be elucidated.

Polymer films can be employed to provide the passive voids for organic molecules. In contrast to the well-defined, solid cages of zeolites, for example, the passive voids usually restrict the motion and conformational changes of the reactant and intermediate within the voids, as the initial free volume of the cavity tends to be smaller than the species considered. This, of course, affects the reactivity and selectivity of the photoreaction. Therefore, the choice of the proper polymer films, in terms of the free volume, shape, wall stiffness, and permeability of the void modulated by the stretching of the films, may provide the best (or at least better) cavities for the desired photoreactions. It is rather unanticipated and hence emphasized that the cavities are templated or memorized for some period of time, even after releasing the initial substrate, and the secondary reactions within the cavities are shown to be controlled by the templated or memorized shape of the voids.

ILs are distinctive and valuable media for a variety of reactions, as they possess charges and are relatively viscous. The typical room-temperature ILs, such as alkylmethylimidazolium salts, have been employed as media for several photoreactions, but precaution should be exercised to avoid the photodecomposition of the ILs themselves by choosing the irradiation wavelength. The photoinduced electron transfer in ILs has been most extensively studied, as the ionic character as well as the viscosity of the media stabilize the radical ion pairs and alter the rates of electron transfer and recombination processes. The control of other types of photoreactions has been also explored.

Other types of less-defined cavities such as microemulsions, micelles, vesicles, and voids in dendrimers, liquid crystals, and organogels have been also exploited for a range of photochemical reactions. Although none of them becomes an exclusive general approach for controlling photochemical outcomes, the alternative media can be fairly attractive when chosen properly for the specific photoreactions.

Götz Bucher

The University of Glasgow

During the last 50 years, matrix isolation spectroscopy (MI) has contributed much to the development of modern physical organic chemistry. It allows the study of a range of interesting molecules, including a variety of reactive intermediates, some excited states, even ions, in an inert and almost noninteracting environment. In a typical MI experiment, a stable photochemical precursor to the reactive molecule of interest is deposited onto a cold spectroscopic window with a large excess of an inert gas, typically argon or other noble gases, but also nitrogen, methane, or carbon dioxide. The precursor is photolyzed, and the reactive intermediate can be investigated by spectroscopy—typically infrared, UV/Vis, and electron paramagnetic resonance (EPR). The advantages of the technique are obvious: the highly inert, rigid, and cold environment not only prevents intermolecular quenching of the reactive molecule to be studied, it also offers very narrow IR band widths, resulting in very high sensitivity and facile interpretation of spectra. Secondary reactions with other molecules can be investigated by adding these to the inert gas used. Annealing of the matrix after photolysis allows for diffusion and thermal reactions to take place. During the last two decades, advances in computer technology and in the design of quantum chemical software have made it possible to reliably calculate IR, UV/Vis, and EPR spectra of small to mid-sized molecules. Comparing spectroscopic information obtained by experiment with calculated spectra meanwhile is standard practice in MI experiments, and nowadays no matrix isolation study is published without extensive supporting calculations. The technique of MI has been reviewed and described authoritatively.^{1,2} This chapter will therefore not deal with technical details of the method, which are summarized elsewhere,² nor will it provide a comprehensive review of all literature available. It will leave out studies that mainly focus on thermal generation of reactive species (by flash vacuum pyrolysis [FVP]), and it will not cover photochemical reactions of transition metal complexes. It will instead concentrate on recent studies on the photochemical generation of reactive intermediates, and on the photochemistry of reactive species, from an organic chemist's perspective.

12.1 Photochemical Generation or Photochemistry of Free Radicals

Simple free radicals are relatively difficult to investigate by MI. Any photochemical cleavage of a precursor molecule will automatically result in the formation of two radical centers, which will usually recombine within the rigid cage of the matrix cavity, resulting in poor radical yields. Potential routes around this problem are found in the use of precursor molecules that yield one stable radical upon photolysis, fragment into a radical pair separated by inert spacer molecules, or generate the radical of interest by FVP.

The phenyl radical **1** is one of the most important species in combustion processes. While it can be generated by photolysis of iodobenzene or dibenzoyl peroxide,³ the FVP of *trans*-azobenzene **2**, followed by trapping of the fragments in solid Ar, provides a cleaner synthesis of **1**. The important reactions of **1** with water and oxygen have recently been investigated.^{4,5} Reaction of matrix-isolated **1** with $^3\text{O}_2$ yields the phenylperoxy radical **3** in a diffusion-controlled process.⁴ Irradiation of **3** with visible light leads to rearrangement of **3** into the 2-oxepinoxy radical **4**, while the phenoxy radical **5** is not formed under the conditions of MI. Extended photolysis of **4** finally yields the ketene radical **6**. If a matrix containing **1** and water is annealed, initially a weak complex **1**/water **7** is formed, which yields a benzene-hydroxyl radical complex **8** upon photochemical excitation.⁵

The 2-hydroxyphenoxy radical **9**, a derivative of **5**, was successfully characterized by photolysis of matrix-isolated 2-nitrophenol **10**.⁶ Irradiation of **10** initially leads to 2-hydroxyphenyl nitrite **11**, which subsequently loses NO to yield **9**. The parent phenoxy radical **5** as well as phenyl nitrite ($\text{C}_6\text{H}_5\text{-ONO}$) had earlier been prepared by irradiation of nitrobenzene.⁷

Broadband irradiation of *i*-propyl nitrite ($(\text{CH}_3)_2\text{CH-ONO}$), matrix isolated in Ar, on the other hand, yields at best trace amounts of the isopropoxy radical. Major products include acetone, acetaldehyde, HNO, and nitrosomethane.⁸ Closely related to the phenoxy radical are the anilino radical,

Ph-NH, and its derivatives. The 4-methylanilino radical 4-MeC₆H₄NH is formed upon photolysis of matrix-isolated *p*-toluidine.⁹

Oxidation of the matrix-isolated vinyl radical **12** with ³O₂ has been reported to yield the vinylperoxy radical **13** in a barrierless reaction.¹⁰ While this finding was not new, the fact that photolysis of **13** results in the formation of a CH₂OH/CO complex **14** clearly came as a surprise. Complex **14** is likely formed by a hydrogen transfer reaction from the H₂CO–HCO radical pair.

12.2 Diradicals

The characterization of diradicals or electron-deficient species such as carbenes, nitrenes, and silylenes has long been a major application of MI. In recent years, MI has also been employed to characterize aromatic σ,σ -diradicals, like *m*- or *p*-benzynes.

12.2.1 Carbenes

Due to the availability of diazo compounds as convenient precursors, MI is ideally suited for the characterization of free carbenes. A large number of different carbenes has been characterized by MI, and the results have been reviewed.^{11,12} Some recent studies deserve mention in this article. In the field of ground-state singlet carbenes, the focus of research has been on carbene rearrangements. Singlet vinylcarbenes represent a very simple class of singlet carbenes. Due to the ease of their rearrangement into allenes or cyclopropenes, there is only very scant information available on these elusive carbenes. If vinylcarbene is stabilized with a chloro substituent as in chlorovinylcarbene **16**, it is sufficiently long lived to be characterized in a nitrogen matrix at $T = 8$ K.¹³ Photolysis of the matrix-isolated diazine **15** initially led to formation of **16**, which upon long-wavelength irradiation ($\lambda = 578$ nm) was converted into a mixture of cyclopropene **17** and allene **18**. Even the synthesis of highly strained *anti*-Bredt olefins like the cyclopropene **21**, from diazine **19** via carbene **20**, was achieved in this study.

In a similar way, singlet and triplet carbenes derived from heterocycles like benzofuran and benzothio-*phene* undergo complex rearrangements that yield cyclopropenes as well as ring-opened products.^{14,15}

Some small-ring carbenes like cyclopropenylidene have been identified as constituents of interstellar matter (IM).¹⁶ Other constituents of IM include linear carbon chains, and carbon chains terminated by nitrile functionalities. In this context, H–C_{*n*}–H chains (*n* being an odd number) represent an

important research target. Photolysis of matrix-isolated diazopentadiyne **22** allowed for the successful characterization of H-C₅-H **23**.¹⁷ According to high-level ab initio calculations, **23** is best described as linear (D_{∞h}) triplet diethynylcarbene, and its reaction with oxygen resulted in the formation of carbonyl O-oxide **24**, where attack of oxygen occurred at the middle carbon atom.

12.2.2 Nitrenes

Nitrenes can be conveniently synthesized by photolysis of organic azides. As these are usually easily accessible, a large body of literature on nitrenes and their rearrangements exists.^{18–21} Oxidation of triplet aryl nitrenes with dioxygen is an interesting aspect of aryl nitrene chemistry that has only recently been investigated in detail. In recent work on the matrix photochemistry of 4-azidoaniline **25**, the reactivity of triplet 4-aminophenylnitrene **26** toward ³O₂ was explored in depth, using both MI and a variety of computational methods.²² Photolysis of **25** in Ar doped with 4% oxygen gave triplet nitrene **26**, which upon annealing the matrix to $T = 35$ K yielded a mixture of the rotameric nitroso O-oxides **27** and **28**. These could be interconverted by monochromatic irradiation. Long-wavelength ($\lambda > 515$ nm) irradiation of **27/28** finally yielded 4-nitroaniline **29**. Importantly, no evidence could be gained for the intermediacy of dioxaziridine **30**, although the formation of such species had been reported before.²³

Nitrene oxidation was also studied by MI in another, somewhat more unusual system. Most nitrenes investigated so far contain a nitrene center connected to a carbon atom. In a few cases, the silyl nitrenes had been investigated.²⁴ Relatively recently, a new class of nitrenes, boryl nitrenes were studied for the first time using MI.²⁵ Photolysis of *B*-azido-catecholborane **31** in Ar matrix yields a triplet ground-state

nitrene **32**, which does not undergo any further photochemical rearrangements. It can be trapped by CO, yielding a boryl isocyanate, and by triplet oxygen. In the latter reaction, a borylnitroso-*O*-oxide **33** is formed, which is very unstable and is rapidly converted into nitritoborane **34** upon extended photolysis.

The electronic structure of **32** is related to difluorovinylidene $\text{F}_2\text{C}=\text{C}$. The resulting extreme reactivity of **32** allows for facile insertion into the D–D bond of deuterium,²⁶ and into the C–H bonds of alkanes and even methane.²⁷ The latter reaction could successfully be worked out into a novel amide synthesis.²⁷

A study on the photochemistry of azido-substituted derivatives of pyridine *N*-oxide promised to be particularly interesting, as both the azido function as well as the pyridine *N*-oxide unit²⁸ are known to be photoreactive. In the case of 4-azidopyridine *N*-oxide **35** solution-phase studies had already shown that the *N*-oxide function was not the primary photoreactive moiety, with 4,4'-azobis(pyridine *N*-oxide) **36** being essentially the only product formed.²⁹ Under conditions of MI, photolysis of **35** yielded the triplet nitrene **37**.³⁰ Particularly revealing is a comparison between the EPR zero field splitting (ZFS) parameters of triplet nitrenes **37** and **38** measured in Ar matrix. While **37** showed an unusually low value for $D = 0.62 \text{ cm}^{-1}$, the D value of **38** was obtained as $D = 1.05 \text{ cm}^{-1}$. This indicates a significant degree of spin delocalization away from the nitrene nitrogen atom in **37**, but not in **38**. Accordingly, the pyridine *N*-oxide moiety significantly stabilizes a nitrene unit if it is in *para*-, but not in *meta*-position relative to the nitrene center. Nitrene **37** is also unusual in that the authors of the study could not obtain evidence for any singlet-nitrene derived chemistry, such as formation of didehydroazepines. Nitrene **38**, on the other hand, readily underwent rearrangement to azacycloheptatetraene *N*-oxides upon prolonged irradiation.³⁰

12.2.3 Borylenes

Borylenes—borane-1,1-diyls—represent a class of hypovalent boron compounds that has for a while been known in the form of transition metal complexes.³¹ In its free, uncomplexed form phenyl borylene **39** was characterized only recently.³² Photolysis ($\lambda = 254$ nm) of phenyldiazidoborane **40**, matrix isolated in Ar, led to the exclusive formation of triplet iminoborylnitrene **41**. If the irradiation of **40** was performed in N_2 or Ne matrices, however, borylene **39** could also be identified as product. Irradiation with light of longer wavelength converted it into benzoborirene **42**.³²

12.2.4 Phosphinidenes

Similar to borylenes, phosphinidenes (compounds of monovalent phosphorus) are mostly known in the form of transition metal complexes.³³ Free triplet mesityl phosphenide **43** had previously been known from a single low-temperature X-band EPR study.³⁴ Recent MI work has confirmed the validity of this early EPR study, and has provided the infrared, UV/Vis, and W-band EPR spectra of **43**.³⁵ Phosphenide **43** can be generated by photolysis of matrix-isolated phosphirane **44**. Extended photolysis results in intramolecular hydrogen abstraction and the formation of phosphetane **45**. Didehydroposphepine **46**, on the other hand, is formed in trace amounts at most. It could only tentatively be identified via UV/Vis spectroscopy.

12.2.5 σ,σ -, σ,π -, and π,π -Diradicals

The characterization of 1,2-, 1,3-, and 1,4-diradicals by MI is considerably more difficult than the investigation of 1,1-diradicals such as carbenes and nitrenes. This is due to the fact that convenient photochemical precursors for these species are lacking. Frequently, the problem can be overcome by subjecting thermal precursors like iodo compounds to FVP. As the biradicals involved are photolabile, secondary photolysis experiments following the initial FVP are frequently performed. σ,σ -Diradicals like *o*-, *m*-, and *p*-benzyne and σ,p -diradicals like $\alpha,3$ -didehydrotoluene have been generated by thermolysis (*o*-, *m*-benzyne) or photolysis of diiodoarenes or diperoxides,^{36,37} and in certain cases by photolysis of quinone diazides.³⁸ This chemistry has been reviewed.³⁹ It will only be touched in this review in the context of oligoradicals (discussed later). *m*-Xylylene **47**, a *meta*-quinoid π,π -diradical, has recently been generated by FVP of α,α' -diiodo-*m*-xylene **48**, and characterized by EPR, UV/Vis, and for the first time also by IR spectroscopy.⁴⁰ Upon irradiation, it undergoes interesting photochemical rearrangements. Initially, a mixture of the strained bicyclic trienes **49** and **50** is formed, while later in the irradiation, tricyclus **51** is also observed.

Photolysis of tetrazole **52**, matrix isolated in a nitrogen matrix at $T = 4.6$ K, resulted in formation of diradical **53**, a triaza-analogue of trimethylenemethane.⁴¹ Being a nondisjoint diradical, **53** is predicted to be a ground-state triplet species, which is confirmed by ESR spectroscopy. IR and UV/Vis spectroscopy confirm this assignment and also rule out the possible formation of the ring-closed isomers **54** and **55**.

12.3 Tri-, Tetra-, and Oligoradicals

MI has been successfully employed in the characterization of molecules with more than two deficient valencies. Di- and trinitrenes as well as -carbenes can be generated by photolysis of the corresponding bis- or tris-azides or -diazo compounds. This chemistry, which involves molecules with a spin multiplicity of up to tridecet, has been reviewed.^{11,42,43} Very challenging, however, still is the characterization of molecules containing both a nitrene or carbene functionality and a free radical center, and of aromatic

σ,σ,σ -, σ,σ,π -, σ,π,π -, or π,π,π -triradicals. A number of nitrene radicals have recently been generated by photolysis of 4-iodo-fluorophenylazides. Cleavage of the carbon–iodine bond and dediazotation results in the formation of the fluorinated *p*-dehydrophenylnitrenes.^{44–47} In the case of 4-iodo-2,3,5,6-tetrafluorophenylazide **56**, photolysis in Ar matrix at $T = 4$ K results in formation of 4-dehydro-2,3,5,6-tetrafluorophenylnitrene **57**, a σ,σ,π -type triradical, in its quartet ground state.^{44–46} The cleavage of the C–I bond is far less efficient than dediazotation. Hence, photolysis of **56** initially results in formation of the triplet nitrene **58** that later either loses the iodine atom, or undergoes a competing rearrangement to didehydroazepine **59**. The efficiency of the photodeiodination reaction of fluorinated iodophenylnitrenes depends on the number of fluorine atoms present in the molecule—a reduced degree of fluorination results in a lesser yield of nitrene radical.⁴⁶ Photolysis of 3-iodo-2,4,5,6-tetrafluorophenylazide **60** in argon or neon matrices, on the other hand, did not allow for a detection of 3-dehydro-2,4,5,6-tetrafluorophenylnitrene **61**. Instead, ring opening of the triplet nitrene **62** (or an isomeric didehydroazepine) to the enallene nitrile **63** was observed exclusively.⁴⁷

Characterizing triradicals of the σ,σ,σ -type by MI represents a serious challenge, as three single bonds need to be broken in order to achieve this aim. A representative example is 1,2,3-trisdehydrobenzene **64**, which was successfully generated by photolysis of 3-iodophthalic anhydride **65**, isolated in a neon matrix at $T = 3$ K. Excitation of **65** with light of a pulsed XeCl excimer laser ($\lambda = 308$ nm) resulted in competing deiodination or decarboxylation/decarbonylation, leading to 3-dehydrophthalic anhydride **66** or iodobenzynes **67**. Switching the excitation wavelength to $\lambda = 248$ nm (KrF excimer laser) then allowed for the characterization of triradical **64**, which eventually loses another hydrogen atom and undergoes ring opening to hexatriyne **68**.⁴⁸ According to high-level ab initio calculations, **64** has a 2A ground state with a short ($r \sim 1.68$ Å) C_1 – C_3 distance that resembles a bicyclo[3.1.0]hexatrien-6-yl radical **68**.⁴⁹

12.4 Photochemical Synthesis of Acenes

With increasing number of annelated rings, linear acenes (naphthalene, anthracene, tetracene, penta-cene, etc.) become progressively unstable. Hexacene requires additional bulky substituents to be stable, and heptacene **69** had been unknown until recently, when it was successfully generated by twofold photodecarbonylation of diketone **70**, first in a polymer matrix⁵⁰ and then in a cryogenic matrix.^{51,52} Remarkably, matrix-isolated samples of **69** undergo charge separation into the radical cation and radical anion of **69** if irradiated with short-wavelength UV light.⁵¹ Similarly, octacene and nonacene could be generated by photolysis of tetraketones in an Ar matrix.⁵³

12.5 Photochemistry of Heterocycles

The last five years have seen a number of MI studies published, in which a variety of different heterocyclic molecules were isolated in inert gas matrices and then subjected to photolysis. This section will give a very brief overview about some of these studies. An important question in heterocyclic chemistry frequently is the issue of the existence of various tautomeric forms of a given heterocycle. Narrow-band irradiation of matrix-isolated samples is an ideal way to change the composition of a tautomer mixture by attaining a novel, photostationary equilibrium. For example, the equilibrium of 2-amino-5-methylpyridine **71** and its imino-tautomer **72** normally completely lies on the side of the amine **71**.

UV irradiation of **71** under conditions of MI allows for the formation and characterization of **72**.⁵⁴ As a sideproduct, the aminyl radical **73** is also observed.

A photochemical conversion of a trithione **74** into a trithiol **75** was observed, when trithiocyanuric acid **74** was UV irradiated under conditions of MI.⁵⁵ The product, trimercaptotriazine **75**, is formed in a remarkable triple photochemical proton transfer reaction.

A different type of tautomer interconversion is observed, if *N*-hydroxypyridine-2-thione **76** is photolyzed in inert gas matrices. UV irradiation of **76** results in cleavage of the N–O bond and formation of two conformers of 2-hydroxysulfanylpuridine **77**.⁵⁶

Carbonyl compounds, and to a lesser degree thiocarbonyls, can undergo photochemical α -cleavage (Norrish type I reaction). The two isomers of monothio- α -pyrone **78** and **79** do not constitute an exception to this rule.⁵⁷ Photolysis of both **78** and **79**, matrix isolated in Ar, results in the formation of ketene-thioaldehydes like **80** or thioketene-aldehydes such as **81**. Interestingly, **80** is converted into **81** via a photochemical hydrogen shift. As a result, **78** and **79** can be interconverted photochemically.⁵⁷

12.6 Photooxidation

The reactions of organic molecules with high-valent metal oxides and oxochlorides play an important role in the repertoire of synthetic organic chemistry. MI can be used to study these reactions, but frequently photoexcitation is required to initiate the oxidation reactions, in which unusual intermediates may be encountered. The photoinitiated reactivity of two oxochlorides, CrO_2Cl_2 (chromyl chloride) and VOCl_3 , toward a range of organic substrates has recently been investigated in detail. Twin-jet deposition of mixtures of CrO_2Cl_2 and benzene with argon gave no evidence for any significant ground state interaction between the substrates. Irradiation ($\lambda < 590 \text{ nm}$) of the mixture, however, resulted in oxygen transfer and formation of a complex **82** of 2,4-cyclohexadienone and CrOCl_2 .⁵⁸ Surprisingly, the more stable $\text{C}_6\text{H}_6\text{O}$ isomer phenol was not formed. A mixture of VOCl_3 and benzene, on the other hand, proved to be photostable. Similar results were obtained in the reactions of chromyl chloride with methylated derivatives of benzene,⁵⁹ and electron-donor⁶⁰ as well as electron-acceptor⁶¹ substituted benzenes. In most cases, the reactions led to exclusive formation of cyclohexadienones complexed to a CrOCl_2 fragment. In the case of certain organic substrates (e.g., benzonitrile⁶¹), formation of the phenols was also observed.

Consistent with the results obtained with arene oxidation, the photochemical reaction of acetonitrile (CH_3CN) with CrO_2Cl_2 or VOCl_3 also led to oxygen atom transfer, yielding complexes of acetonitrile *N*-oxide CH_3CNO with CrOCl_2 or VCl_3 , respectively.⁶² Chloroethenes also undergo photoinitiated oxidation with chromyl chloride.⁶³ In these reactions, an oxygen atom is transferred to the higher substituted carbon atom, and a hydrogen or chlorine atom is shifted to the lesser substituted carbon atom. Oxidation of vinyl chloride thus yields a complex of acetyl chloride with CrOCl_2 . In contrast, oxidation of bromoethene with chromyl chloride yields the complex of bromoacetaldehyde with CrOCl_2 .⁶⁴ Remarkably, a different regioselectivity is thus observed in the photooxidations of chlorinated and brominated derivatives of ethene. Photochemical reactions between chromyl chloride and organic substrates are not limited to those bearing reactive functional groups. Even pure alkanes such as cyclohexane,⁶⁵ cyclopentane, and cyclopropane⁶⁶ undergo the reaction. With cyclohexane, oxygen atom transfer to produce cyclohexanol takes place,⁶⁵ whereas the photooxidation of cyclopropane results in cleavage of the three-membered ring and formation of a formaldehyde- CrOCl_2 complex and ethene.⁶⁶

In contrast to the clean reactions observed with chromyl chloride, the photooxidation of cyclohexene with ozone yielded products indicative of formation of $\text{O} (^3\text{P})$.⁶⁷ Thermal reaction of ozone and cyclopentadiene, on the other hand, resulted (among others) in the formation of a Criegee intermediate (carbonyl *O*-oxide)—the first time that this type of reactive intermediate had been directly observed as a result of an ozonolysis reaction.⁶⁸

12.7 Conclusion

MI studies have frequently employed photochemical excitation of photolabile precursors (azides, diazo compounds, and diazirines) in order to generate reactive intermediates of interest. This type of research, in which photochemical excitation serves as a tool continues today, as the ever-growing research areas of nitrene and carbene chemistry (among others!) demonstrate. More recently, research efforts have somewhat changed their accentuation, with MI being increasingly utilized to elucidate pathways in little-explored photochemical reactions. This new development is certainly in part due to the rapid development of computational chemistry and of computer technology, which nowadays allows for the

identification of photochemical reaction products by simple comparison of experimental and calculated IR spectra. More than 50 years after its invention,⁶⁹⁻⁷¹ MI still is a technique that is employed inventively, yielding results that are published in the topmost scientific journals.⁷²

13.1 Introduction

The chemical conversion and utilization of solar energy is a central topic of general photochemistry. In addition to solar water splitting, the “holy grail” of photochemistry, also cleaning of air and water through aerial photooxidation, fixation of nitrogen and carbon dioxide, and organic syntheses have received considerable attention in research of the last three decades. In general, the most relevant primary reaction steps are the light-induced generation of charges followed by their utilization in electron exchange reactions with substrates. Whereas many systems easily undergo the first step, charge recombination usually prevents the second step, which is essential for the chemical utilization of light energy. The crucial point in the development of an efficient system is therefore how to slow down recombination in favor of electron exchange. Depending on the detailed nature of the system involved, in many cases a sensitizer is necessary to allow utilization visible light, which constitutes about 45% of the solar light arriving at the earth’s surface.

An elementary electron transfer reaction $A + D = A^{\bullet-} + D^{\bullet+}$ in principle can be sensitized by both a homogeneous and a heterogeneous photosensitizer. Typical examples for the former are organic compounds or metal complexes having charge-transfer (CT) character. Their basic action can be described

by Equations 13.1 through 13.6 wherein Red and Ox symbolize electron-donating and electron-accepting groups usually connected through a covalently linked molecular bridge. These groups favor the photo-induced charge generation (Equation 13.1) whereas the bridge may be able to slow down the undesired charge recombination converting the chemically valuable redox energy of $A^{\bullet-} \cdots D^{+\bullet}$ into useless heat (Equation 13.2). Only if this reaction is slower than electron exchange with substrates, efficient formation of the usually labile primary intermediates $A^{\bullet-}$ and $D^{+\bullet}$ may occur (Equation 13.3). Their further transformation to the final redox products A_{red} and D_{ox} has to be fast and irreversible (Equations 13.4 and 13.5) in order to avoid back electron transfer (Equation 13.6):

Although a great variety of molecular photosensitizers ranging from simple intramolecular CT compounds to supramolecular systems are known to undergo photoinduced charge generation,¹ only a very few can induce redox reactions with substrates since usually charge recombination and back electron transfer are too efficient.² Contrary to this, heterogeneous photosensitizers of semiconductor character enable also the chemically most important electron exchange with substrates. By analogy with the molecular sensitizer discussed earlier, the basic reaction steps may be summarized in a simplified way according to Equations 13.7 through 13.9. Light absorption generates, inter alia, reactive electron-hole pairs trapped at the surface. It is expected that the distance between these redox centers should be larger than in a molecular sensitizer and therefore charge recombination may become slow enough to allow the desired interfacial electron transfer (IFET) between the solid and dissolved substrates. The further reaction steps are described by Equations 13.4 through 13.6.

It is noted that no general agreement exists on the definition of the term *photocatalysis*. Generally, it implies that light and a catalyst are necessary to induce or accelerate a chemical transformation³⁻¹³ as also expressed by the IUPAC recommendation, according to which photocatalysis is the “change in the rate of a chemical reaction or its initiation under the action of ultraviolet, visible or infrared radiation in the presence of a substance—the photocatalyst—that absorbs light and is involved in the chemical transformation of the reaction partners.”¹⁴ This definition includes *photosensitization*, “a process by which a photochemical alteration occurs in one molecular entity as a result of initial absorption of radiation by another molecular entity called photosensitizer,”¹⁵ but it excludes the photoacceleration of a stoichiometric thermal reaction, irrespective of whether it occurs in homogeneous solution¹⁶ or at

the surface of an illuminated electrode,¹⁷ otherwise any photoreaction would be catalytic. The catalytic nature of a heterogeneous reaction is given when the turnover number, that is, number of molecules reacted divided by the number of active sites, is larger than 1.¹⁸ Is it only one or smaller, it may be called semiconductor-assisted photoreaction, by analogy with homogeneous catalytic reactions.^{19,20} However, the number of active sites of a semiconductor photocatalyst powder is usually unknown.* Therefore, in almost all cases the differentiation between a catalytic and *assisted* photoreaction may be impossible. Accordingly, many of the photoreactions conducted in the presence of semiconductor powders and claimed to be “photocatalytic,” in reality are semiconductor-assisted photoreactions.²¹ Especially if few micromoles of products are produced in the presence of a much larger amount of semiconductor powder and its reusability was not proven.

A further problem of definition arises when not the semiconductor itself but a substrate or a semiconductor–substrate CT complex (vide infra) is the light-absorbing species. We have proposed to use the terms *direct* and *indirect semiconductor photocatalysis*.²² As well known from thermal heterogeneous catalysis, the pristine surface may be restructured in the very early reaction stages to the catalytically active one having different light absorption properties.

Photoelectrochemistry, the photogeneration of charge and current at semiconductor electrodes in contact with a liquid electrolyte,²³ can be considered as the basis for semiconductor photocatalysis. For a rather large semiconductor single crystal it is generally assumed that the presence of a space-charge region (band-bending) is necessary to explain the charge-separating properties of the semiconductor–liquid interface. For a critical discussion of the basic theories and their underlying assumptions, the reader is referred to review articles.^{24–26} Inspired by the early observation of Bard et al., that irradiation of titania powder suspended in a liquid solvent promotes electron-transfer reactions of substrates in solution,^{27–30} a great variety of chemical transformations in the presence of semiconductor powders or colloids has been reported.^{31–34} Some of these reactions are related to prebiotic chemistry like the TiO₂-^{35,36} or CdS-assisted³⁷ photoreduction of N₂, the generation of amino acids from CH₄, N₂, H₂O in the presence of platinized TiO₂,³⁸ and the TiO₂- or CdS-induced peptide formation from glycine.³⁹ The fading of paints⁴⁰ and the already technically applied aerial detoxification of water and air^{41,42} illustrate important technical and environmental aspects of semiconductor photocatalysis.

Common to all these chemical processes is that well-known products were formed in very low yields and rather identified only spectroscopically than isolated. Although high “quantum yields” were claimed in a few cases, it is mentioned that quantum yields in heterogeneous systems are extremely difficult to obtain due to the problem of varying light reflectance. Furthermore, quantum yields are measured at short irradiation times and therefore do not give information on the synthetic usefulness of the reaction. In general, photocorrosion, the self-destruction of the semiconductor by the light-generated charges, often prevents a long-term reaction, indispensable to obtain the products on a preparative scale. In this chapter we shall therefore focus on the question if semiconductor photocatalysis at all is a useful alternative synthesis method and whether or not it may open novel pathways for chemical synthesis.

13.2 Photocatalysis at Semiconductor Powders

13.2.1 Fundamentals

The use of a metalized semiconductor particle as a kind of “short-circuit” microphotoelectrochemical cell was introduced through the work of Bard et al. on the photo-Kolbe reaction.⁴³ In this system, a few weight percent of a noble metal, most often platinum, covers the surface of a semiconductor powder like titania. Light absorption generates an electron at platinum and a hole in the valence band of titania constituting cathodic and anodic surface centers. Differences to the macroelectrodes employed in photoelectrochemistry have been discussed.^{25,44–47} It is noted that platinization in many but not in all cases is required in

* It was proposed to take the number of molecules present in one monolayer, about 10¹⁴ per cm², as an estimate; Ref. [17].

SCHEME 13.1 Primary processes occurring upon photoexcitation of CdS in the presence of an acceptor A and donor D. Conduction (CB) and valence band (VB) have Cd5s and S4p character, respectively. The thick vertical bar symbolizes the solid/liquid interface.

order to obtain acceptable reaction rates. Scheme 13.1 summarizes the early processes occurring in the elementary redox reaction $A + D = A^{\bullet-} + D^{\bullet+}$ photocatalyzed by cadmium sulfide.

The light-generated electron-hole pair, which is initially delocalized throughout the crystal in general, undergoes a fast relaxation to the conduction band edge. From there, radiative and nonradiative charge recombination without ($h\nu_1$) or with intermediate trapping at surface states ($h\nu_2$)* dominates over trapping in the form of reactive electron-hole pairs (e_r^-/h_r^+). Only from the latter electron change with A and D may proceed. For simplicity another, but important primary process, so-called photocorrosion is omitted. It consists of electron exchange with the semiconductor lattice ions inducing a destruction of the photocatalytically active surface (vide infra). The lifetimes indicated in Scheme 13.1 originate from colloidal TiO_2 . Rather long is the lifetime of a few microseconds reported for trapped electron-hole pairs.⁴⁸ IFET reactions may proceed in the range of picoseconds as illustrated by the values of 18 and 200 ps measured for the IFET from e_r^- to a viologen and from diethyldithiocarbamate to h_r^+ , respectively.⁴⁹ It is generally assumed that due to the short lifetime of the light-generated charges, only adsorbed substrates can undergo an efficient electron exchange. However, in the case of titania, photocatalyzed aerial oxidation of benzyl alcohol and rhodamine B weakly adsorbed substrates react faster than stronger adsorbed ones.⁵⁰⁻⁵³ It is known that in such type of oxidations the electron-accepting substrate may be located even a few millimeters away from the surface.⁵⁴ As mentioned earlier, the primary redox products $A^{\bullet-} + D^{\bullet+}$ are converted in fast secondary reaction steps to A_{red} and D_{ox} , the oxidized and a reduced final product. A corresponding energy diagram is depicted in Scheme 13.2, assuming that the IFET of adsorbed substrates is rate determining. Thus, considering the reactive electrons and holes as types of photogenerated cathodes and anodes, the overall reaction can be viewed as photoelectrolysis.

Since in this basic reaction mechanism light is absorbed by the semiconductor, it may be termed just as semiconductor photocatalysis or more detailed as direct semiconductor photocatalysis. Alternatively, when only the substrate is the light-absorbing component, the mechanism of indirect semiconductor photocatalysis may operate. The two mechanisms are schematically depicted in Scheme 13.3 for titania photocatalysis.

In the direct pathway the electron-hole pair generated by the photon $h\nu_1$ is separated into reactive electrons and holes. The former reduces oxygen to superoxide, which is finally transformed to the strongly oxidizing OH radical. Simultaneously the reactive hole oxidizes water to another OH radical or the donor D to its radical cation, which is converted to stable oxidation products through a multi-step reaction cascade including participation of the OH radical. When D is a typical water pollutant

* Surface states are defined as localized energy states, in contrast to energy levels in the conduction and valence band which are delocalized throughout the crystal.

SCHEME 13.2 Energy diagram of the elementary redox reaction $A + D = A_{\text{red}} + D_{\text{ox}}$.

SCHEME 13.3 Direct ($h\nu_1$) and indirect ($h\nu_2$) semiconductor photocatalysis of the aerial oxidation of D. The two horizontal lines designate the upper valence and lower conduction band edges; corresponding redox potentials are referenced vs. NHE and refer to a titania particle in contact with water of pH 7.

like phenol, complete oxidation to carbon dioxide and water is observed. In the indirect pathway light absorption of a photon $h\nu_2$ by D generates the excited state D^* followed by electron injection into the conduction band if its redox potential is equal or more negative than the conduction band edge. The resulting e_{in}^- has to perform a fast reduction of oxygen in order to prevent charge recombination with D^+ . Further conversion to final products proceeds as discussed earlier.

An early example for both mechanisms is the exhaustive dealkylation of methylene blue (MB) and rhodamine B^{55,*} photocatalyzed by cadmium sulfide (Scheme 13.4). Dealkylation of MB (**1**) to the

SCHEME 13.4 Overall reaction and key mechanistic steps in the dealkylation of methylene blue photocatalyzed by CdS.

* Here and in the following, the use of the chemical formula indicates that the semiconductor was present as a powder suspension.

diamine **2** occurs only if light is absorbed by CdS and not by MB. In the mechanism proposed for MB, the reactive hole oxidizes the dye to the corresponding radical cation **1a** and a proton whereas the reactive electron reduces oxygen to superoxide. Subsequently the strongly reducing α -amino radical **1a** injects an electron into the conduction band of CdS. Such type of electron injections is well known in photoelectrochemistry (current amplification effect).^{56a,*} The produced methyleneiminium salt **1b** in the final step is hydrolyzed to the trimethyl derivative **1c** and formaldehyde. Repeating this typical reaction cycle three times eventually leads to the fully dealkylated product **2**.

Contrary to this, RhB is also dealkylated when only the dye is the light absorbing component. In this case the excited state redox potential of the dye is negative enough to inject an electron into the conduction band affording the radical cation of RhB. The injected electron reduces oxygen and the radical cation again undergoes full dealkylation as discussed for MB. Thus, like in the direct photocatalysis of MB also the indirect photocatalysis affords the same type of reaction product. It is noted that in the latter case the semiconductor plays the role of an electron relay, enabling a fast reduction of oxygen. A similar indirect photocatalysis mechanism may operate also when one of the substrates forms a CT complex with the semiconductor surface leading to a new electronic absorption band. A unique example is the titania-catalyzed photosulfoxidation of *n*-heptane by sulfur dioxide and molecular oxygen affording *n*-heptane sulfonic acid. The reaction proceeds with visible light although all reaction components absorb only in the UV. It was shown that sulfur dioxide forms a CT complex with titania enabling absorption by visible light.^{56b}

13.2.2 Thermodynamic Aspects

Scheme 13.5 summarizes the thermodynamic requirements of direct photocatalysis for the case of an *n*-type semiconductor.⁵⁷

Absorption of light of energy equal or larger than the bandgap E_g induces a splitting of the Fermi level into quasi-Fermi levels of electrons and holes indicated as nE_F^* and pE_F^* , respectively. Since redox reactions are connected with reorganization energies (χ), the density of states has a maximum not at the standard potential ($D_{red,ox}$ and $A_{red,ox}$) but at an energy higher (D_{ox} and A_{ox}) and lower (D_{red} and A_{red}) by the amount of χ . Therefore both reductive and oxidative IFET reactions are thermodynamically feasible only when the energies of A_{ox} and D_{red} are equal or below the quasi-Fermi level of electrons and holes, respectively. Whereas standard potentials are usually easy obtainable, this is not true for reorganization energies, which may reach values of up to 1 eV. Thus, a large uncertainty is connected with a precise evaluation of the free energy change of such type of interfacial electron exchange reactions.

SCHEME 13.5 Thermodynamics of interfacial electron transfer (IFET) between a photoexcited semiconductor solid and dissolved donor and acceptor molecules. Dotted and empty boxes indicate occupied and empty valence and conduction bands, respectively.

* A classical example is also the hole oxidation of ethanol. $\text{CH}_3\text{CH}_2\text{OH} + h^+ = \text{CH}_3\text{CHOH} + \text{H}^+$, $\text{CH}_3\text{CHOH} = \text{CH}_3\text{CHO} + \text{H}^+ + e_{cb}$.

SCHEME 13.6 Bandgaps and band edge positions of some semiconductor single crystals and powder in contact with neutral water. ZnS,¹⁵³ CdS,¹⁰⁴ and TiO₂.²¹²

The positions of the quasi-Fermi levels can be estimated from the band edges, which are known for the most commonly applied semiconductor powders as summarized in Scheme 13.6. Depending on the amount of doping, they are located a few tenths of an electron Volt below or above the conduction and valence band edge, respectively. It is noted that band edge positions of oxidic and sulfidic semiconductors strongly depend on the presence of impurities and on the solvent they are suspended in. Increasing the pH value of water induces a cathodic shift of the band edges by 0.059 V/pH unit. Similarly, substituting neutral water by, for example, acetonitrile the quasi-Fermi level is shifted by about 1.0 V.⁵⁸ In the case of CdS removal of traces of elemental sulfur and cadmium from the surface results in a cathodic shift of 1 V.⁵⁹ Adsorption of neutral thiols has no influence, whereas thiolate ions shift the Fermi level by 0.4 V cathodically.⁶⁰

From the earlier discussion it follows that for a given semiconductor photocatalyzed reaction the variation of catalyst preparation, kind of solvent, and adsorption properties of substrates may induce a considerable shift of band positions. The estimation of the driving forces for the two IFET reactions is therefore connected with a large uncertainty. However, in spite of neglecting mutual kinetic barriers, in many cases it rationalizes the observed experimental results. An example is the photooxidation of lactic acid. Whereas platinized TiO₂ catalyzes oxidation to acetaldehyde and carbon dioxide, platinized CdS induces oxidation of only the OH group affording pyruvic acid. This is in accord with the less oxidizing property of $h\nu^+$ since the valence band edge of CdS is located about 0.5 V more cathodic as compared to TiO₂.⁶¹ Another possibility to introduce chemoselectivity is to vary the substrate's reduction potentials but keep the photocatalyst constant. It was reported that introduction of two methoxy groups in the para-positions of benzophenone shifts the reduction potential to the negative of the conduction band edge of highly pure cadmium sulfide and thus prevents the reduction to alcohols by water as observed with other aromatic ketones.⁶²

13.2.3 Quantum Yield, Surface Area, Temperature, and Light Intensity

Due to the heterogeneity of the reaction system, kinetic experiments and other standard mechanistic experiments are not as straightforward to conduct and interpret as in homogeneous photochemistry. Especially, quantum yield determinations are ambiguous since it is difficult to correct for the amount of light scattered by the photocatalyst powder in order to obtain the amount of light absorbed. The latter may therefore significantly vary from experiment to experiment depending on the type of photoreactor and on the nature of the suspension. Scattering may lower the effective absorbed light intensity by

FIGURE 13.1 Reaction rate as function of photocatalyst concentration.

15%–80%.⁶³ Therefore, all quantum yields reported in the literature are in reality apparent quantum yields and can be compared only qualitatively. Various attempts have been made to overcome these problems^{63–65} in order to allow a better comparison. The most important proposal is to calculate a so-called photonic efficiency and relative photonic efficiency by using instead of the absorbed light intensity the incident intensity, that is, intensity of light arriving at the reaction suspension.⁶⁴ However, this makes sense only if it is assumed that the fraction of scattered light is the same in every experiment, which is rather unlikely.⁶⁶ It seems therefore more practical to compare reaction rates obtained under optimized experimental conditions. This can be easily done by measuring the rate as a function of photocatalyst concentration. A typical example is shown in Figure 13.1 for a photocatalyst powder of specific surface area of $150 \text{ m}^2 \text{ g}^{-1}$.⁶⁷ Reaching a concentration above 4 g L^{-1} apparently light absorption is saturated and the reaction rate does not further increase. The resulting optimum rate is a reasonable measure for comparing the efficiencies of various photocatalytic reactions.

The following qualitative discussion of the quantum yield of a reaction photocatalyzed by a semiconductor powder illustrates these problems in more detail.

Assuming that the efficiency of formation of the reactive electron hole pair (η_r), the efficiency of the IFET (η_{lifet}), and the efficiency of product formation from the primary redox products (η_p) are given by the ratio of the rate constants for formation and consumption of the

$$\eta_r = \frac{k_3}{k_1 + k_2 + k_3} \quad (13.10)$$

$$\eta_{\text{lifet}} = \frac{k_{6,7}}{k_5 + k_{6,7}} \quad (13.11)$$

$$\eta_p = \frac{k_{9,10}}{k_8 + k_{sb} + k_{9,10}} \quad (13.12)$$

$$\text{rate} = \Phi_p I_a = \eta_r \eta_{\text{lifet}} \eta_p I_a \quad (13.15)$$

SCHEME 13.7 Schematic description of primary processes occurring during a semiconductor-photocatalyzed redox reaction. For the sake of simplicity photocorrosion is omitted. Light absorption and primary recombination (1); trapping at unreactive (2) or reactive (3) surface sites; secondary recombination (4,5); IFET processes (6,7); primary back electron transfer (8); secondary reactions (9,10).

corresponding intermediate (Equations 13.10 through 13.12, see Scheme 13.7); k_{sb} denotes the rate constant for the secondary back-electron transfer according to Equations 13.13 and 13.14), the rate of reaction is obtained according to Equation 13.15, wherein I_a denotes the intensity of absorbed light. Accordingly, the quantum yield of product formation, Φ_p , can be formulated as the product of $\eta_r \times \eta_{ifet} \times \eta_p$ and it is difficult to prove which term is decisive. The last term may be relatively independent on small changes of the semiconductor properties, whereas the two other terms can change considerably. Rather minor alterations during synthesis of the powder and adsorption of reaction components can strongly affect the photophysical properties of the semiconductor-liquid interface. Furthermore, when the quantum yields for various substrates are compared, it is difficult to relate observed changes to a specific process of the multistep reaction. In most cases, it is also unknown if electron-hole pairs observed by emission spectroscopy are identical with the reactive electron-hole pairs involved in the IFET reactions. Emission quenching and reaction inhibition studies offer a simple possibility to decide between these possibilities (see Section 13.3.2).

The dependence of apparent quantum yields on light intensity can be characterized by two limiting cases.⁶⁸ At high intensity,* it increases linearly with the square root of the reciprocal intensity. This dependence is typical for homogeneous and heterogeneous photoreactions where recombination of primary products predominates. It has been observed for the TiO_2 -catalyzed photooxidation of isopropanol,⁶⁸ the TiO_2/Pt -catalyzed photo-Kolbe reaction,⁶⁹ and the CdS -catalyzed photoisomerization of *cis*-stilbene.⁷⁰ At low light intensity, the quantum yield becomes independent on I_a and the reaction rate increases linearly with the first power of I_a . This is observed when the aforementioned reactions^{68,70} are conducted at low light intensities.

From the earlier discussion, it is obvious that Φ_p may differ considerably upon minor changes in photocatalyst preparation and solution composition. Higher light intensities may increase recombination,⁷¹ and photophysical processes like emission are strongly influenced by adsorbed impurities.^{72,73} It has been reported that grinding of ZnS powder enhances its photocatalytic activity in the isomerization of olefins⁷⁴ through the generation of reactive surface states, probably some kind of sulfur radicals. Once formed, these catalyze the $[2 + 2]$ cycloaddition of phenylvinyl ether even in the absence of further irradiation.⁷⁵

Increasing the temperature may influence the slowest chemical reaction step and adsorption equilibria of substrates and products. Depending on the relation of the two latter steps and on the temperature

* A typical value for a given set-up is $\geq 10^{15}$ photons/s.

range investigated, the measured activation energy, E_a , may be zero and larger or smaller than zero.⁷⁶⁻⁷⁹ Since these factors depend on the detailed nature of the photocatalyst, minor modifications may induce variations of E_a . Accordingly, values of about 2 and 4 kcal mol⁻¹ were reported for two different CdS samples used in the photodimerization of *N*-vinylcarbazole.⁸⁰

The specific surface area of the semiconductor powder may influence the rate of product formation through two opposite effects.⁴⁰ One is concerned with the rate of electron-hole recombination, which increases linearly with surface area, and accordingly the reaction rate should decrease. The other is a linear increase of the IFET rate due to increasing concentration of adsorbed substrates per unit volume, which should also increase the product formation rate. It is therefore expected that, depending on the nature of semiconductor and substrates, the reaction rate, or apparent Φ_p , may be constant, increase or decrease with increasing surface area. This is nicely reflected by the CdS/Pt catalyzed photoreduction of water by a mixture of sodium sulfide and sulfite. Highest Φ_p values are observed at small surface areas and are constant up to 2 m² g⁻¹. From there a linear decrease to almost zero at a specific surface area of 6 m² g⁻¹ takes place. Upon further increase to 100 m² g⁻¹ this low quantum yield stays constant.⁸¹ Besides the rate also the chemoselectivity may depend on the surface area, which is usually determined by the particle size.* Especially the possibility whether one or more electrons are transferred from and to substrates may be decided by the particle size as illustrated by the ZnS-catalyzed photooxidation of aqueous ethanol.⁸² It was found that only nanometer-sized ZnS induces the formation of the 1h⁺-oxidation product 2,3-butanediol, whereas the 2h⁺-product acetaldehyde is produced by both photocatalysts.

13.2.4 Photocorrosion

Already in 1922, Lenard observed a darkening of the white pigment lithopone, a mixture of zinc sulfide and barium sulfate, upon exposition to sunlight. He assumed that the photocorrosion reaction afforded sulfur and metallic zinc.⁸³ Later it was shown that the presence of water is necessary for this process.⁸⁴ Quantitative investigations revealed the additional formation of hydrogen, zinc sulfate, and zinc hydroxide.⁸⁵ The decomposition of photoexcited ZnS into its elements is a consequence of the quasidelement electronic configuration "Zn(0)S(0)" of the lowest lying electron-hole pair.⁸⁶ Due to the highly covalent Zn-S bond, the effective charges of zinc and sulfur in the ground state can be assumed as +1 and -1, respectively.⁸⁶⁻⁸⁸ Since valence and conduction band have sulfur 3p and zinc 4s character, respectively,^{89,90} the calculated quasidelement nature of photoexcited ZnS becomes explainable. Cadmium sulfide behaves very similar and its mechanism of photocorrosion will be briefly discussed.⁵⁹ In the absence of air, anodic photocorrosion (Equation 13.16)

affords elemental sulfur and cadmium ions, which are reduced to cadmium metal upon prolonged irradiation (Equation 13.17):

This latter reaction competes with the reduction of lattice metal ions (Equation 13.18).

In the case of ZnS or platinized CdS powder, the reduction of water is a further competitive process (Equation 13.19):

* Note that only for nonporous materials does the surface area increase with smaller particle size; however, most of the powders employed are very porous.

In the presence of air, at short illumination times the overall reaction is described by Equation 13.20:

All these photocorrosion processes are of course undesired and it is obvious that their relative importance strongly depends on the presence of surface states, which may facilitate recombination or redox reactions with adsorbed substrates. It is well known from ESR^{71,72,91} and emission spectra⁹² that most of these metal sulfide powders contain surface states. They are introduced during preparation of the powder as a result of lattice defects,^{74,93} trapped holes,⁹¹ surface impurities,⁹⁴ and during the catalytic reaction as a consequence of irradiation and substrate adsorption. Different from metal sulfide semiconductors, titanium dioxide is quite photostable.

13.2.5 Photocatalyst Preparation and Characterization

From the results presented in the previous paragraphs of this chapter, it follows that photocatalytic activity and chemoselectivity of a semiconductor photocatalyst should depend on intimate details of preparation. In addition to careful description of the synthetic details, it is important to characterize the obtained powder by bulk and surface elemental analysis, by determination of crystal structure, specific surface area and surface charge, by ESR and electronic absorption and emission spectroscopy, and by photoelectrochemical experiments to prove the semiconducting properties. The latter are of special importance in order to disfavor a general heterogeneous catalysis mechanism, which usually does not involve simultaneous reductive and oxidative interfacial electron transfer steps.^{95,96} Their involvement may be demonstrated by the effects of electron and hole scavengers added to the reacting system. In the following, we briefly summarize the most important physical properties of the ZnS and CdS powders employed as photocatalysts in the syntheses of novel organic compounds (*vide infra*).

13.2.6 Pristine Semiconductor Photocatalysts

Zinc sulfide is easily prepared from sodium sulfide or thiourea and zinc sulfate under an argon atmosphere. Working in the presence of air introduces traces of zinc oxide, which promotes photocorrosion. The resulting porous powder contains 2%–3% water,⁹⁷ has a specific surface area in the range of 100–170 m² g^{−1}, and consists of 1–10 μm large particles composed of cubic nanocrystals.⁹⁸ Elemental analyses of the bulk materials afford the ratio Zn/S = 1.00/0.97, whereas surface analyses reveal values of Zn/S = 1.00/1.35 to 1.00/1.60. This significant excess of surface sulfur is most likely responsible for the pronounced photostability of these samples even when irradiated in an aqueous suspension in absence of any other substrate. Contrary to that, zinc sulfide, which has a surface excess of zinc, immediately suffers photocorrosion.⁹⁴ Diffuse reflectance spectroscopy indicates a weak subband gap absorption starting at about 400 nm followed by the steep onset of the band-to-band absorption at 360 nm; in some cases, a weak absorption maximum is observable at 450 nm, most likely due to the presence of surface sulfide species.⁹⁴ Accordingly, the emission spectrum of the powder, in addition to the band-gap emission at about 360 nm, contains broad bands around 400 and 490 nm, which originate from recombination of the electron–hole pair scavenged at shallow and deep traps within the band gap.^{94,99} Further emissions at 525 and 690 nm are due to traces of zinc oxide. At higher concentrations, ZnO completely inactivates the photocatalyst. Slightly different to the dry powders, the emission spectrum of an aqueous ZnS suspension exhibits in addition to the band-to-band emission only one further band at 430 nm. This self-activated emission^{100–102} is generated by excess surface zinc ions (sulfur vacancies) as indicated by its disappearance upon addition of sulfide ions.¹⁰³ From the difference to the bandgap energy of 3.6 eV, one can estimate that the corresponding surface state is located about 0.7 eV below the conduction band edge, that is, at a potential of −1.1 V (at pH 7). A value of −1.0 V was reported for colloidal zinc sulfide.⁸²

FIGURE 13.2 Photocurrent spectra of a CdS-covered indium tin oxide (ITO) conducting glass electrode (0.5 V vs. Ag/AgCl) as obtained upon chopped irradiation (light and dark phases were 15 s); supporting electrolyte 0.1 M NaOH (A) and 0.1 M NaOH + MeOH (B).

The n-type character of these zinc sulfides is indicated by the observation of an anodic photocurrent upon illumination of a powder-coated electrode.

Cadmium sulfide is prepared from sodium sulfide and an aqueous ammonia solution of cadmium sulfate. Similarly to the self-prepared zinc sulfide, the obtained powder contains 2%–3% water, has specific surface areas of about $160 \text{ m}^2 \text{ g}^{-1}$, and consists of cubic nanocrystals forming micrometer large aggregates. n-Type semiconductor behavior is indicated by observation of an anodic photocurrent upon irradiating a CdS/ITO powder electrode at wavelengths of 330–650 nm (Figure 13.2).

It is noted that the bandgap absorption of CdS starts at 520 nm. Addition of methanol induces photocurrent amplification with a factor of about 2, irrespective of the energy of excitation. From measurement of the quasi-Fermi potential according to the slurry method,^{104,105} the position of the conduction band edge at pH 7 is found to be at -0.4 V (NHE).¹⁰⁶ Values of -0.27 to -0.29 V were reported for other cadmium sulfide powders.^{104,105}

13.2.7 Grafted Semiconductor Photocatalysts

In addition to pristine semiconductor powders, also photocatalysts supported onto a carrier may be beneficially employed. The idea is that substrate adsorption at the support may increase adsorption at the semiconductor surface and therefore also the reaction rate. A slight improvement is observable, when mixed oxides of $\text{TiO}_2/\text{SiO}_2$ prepared by a sol-gel method are used in the oxidation reactions.^{52,53} The genuine photochemical properties of the semiconductor like bandgap and Fermi level are not altered in this case. However, when the semiconductor is not just ground with silica but grafted onto it, that is, chemically bound, bandgap and Fermi level change and the reaction rate is much stronger affected. In the case of CdS grafted by 12 wt% onto silica, the bandgap is enlarged by 0.20 eV (Figure 13.3) and the quasi-Fermi level shifts cathodically from -0.38 V to -0.59 V (at pH 7).¹⁰⁷ In the case of titania grafted by 13 wt% onto silica the bandgap widening is the same but the quasi-Fermi level is shifted anodically from -0.51 to -0.31 V (at pH 7). Contrary to the mechanically prepared mixture the two components are linked together by Cd–O–Si and Ti–O–Si bonds inducing an electronic semiconductor-support interaction (SEMSI effect) and as consequence thereof a considerable change of intrinsic semiconductor properties. The grafted photocatalysts are easily prepared by impregnating silica with cadmium ions or alkoxytitanates followed by precipitation with sodium sulfide or hydrolysis. Whereas the resulting CdS-12/SiO₂ (Figure 13.3) photocatalyst is twelve times more active than pristine CdS, TiO₂-13/SiO₂ is about four times slower than unmodified titania.^{107,108} Higher amounts of loading afford less active

FIGURE 13.3 Decreasing the amount of CdS grafted onto silica increases bandgap and reaction rate. CdS(A, $v_{\text{rel}} = 1$), CdS-50/SiO₂(B), CdS-30/SiO₂(C), and CdS-12/SiO₂(D).

photocatalysts (Figure 13.3). The most active CdS-12/SiO₂ exhibits also the largest bandgap widening. This contrary effect of grafted CdS and TiO₂ on the photocatalytic activity agrees with the results of time resolved photocharge measurements on the two grafted photocatalysts embedded in an organic polymer matrix. After laser excitation at 337 nm, a multiexponential decay is observed, which is composed of a fast surface (ns) and slow bulk (μs) component. The decay constant of the fastest process decreases from $11 \times 10^6 \text{ s}^{-1}$ for CdS to $2 \times 10^6 \text{ s}^{-1}$ for CdS-12/SiO₂, corresponding to lifetimes of 90 and 500 ns.¹⁰⁹ Thus, the SEMSI effect increases the charge-carrier lifetime and therefore the IFET reaction becomes faster. Contrary to that, the lifetime of the light-generated charges in TiO₂-13/SiO₂ is shortened below the detection limit of 40 ns.¹⁰⁸

Quasi-Fermi levels of the various powder samples are easily obtained by measuring the photovoltage of a semiconductor suspended in aqueous solution of the pH-independent redox system MV^{2+/+} as function of pH value.^{105,111} The method is based on the cathodic shift of the Fermi level upon decreasing proton concentration. At the inflection point the quasi-Fermi level and the methylviologen reduction potential are identical. A lower pH₀ value corresponds to a more negative flatband potential.

Whereas the quasi-Fermi level of -0.38 V measured for CdS-50/SiO₂ does not differ from that of unsupported CdS, it is shifted to -0.41 and -0.59 V in the case of CdS-30/SiO₂ and CdS-12/SiO₂, respectively (Figure 13.4). In the same sequence, the relative initial rate¹⁰⁷ increases from 1.0 to 12 (Figure 13.3). Since the 10-fold rate increase exhibited by CdS-50/SiO₂ cannot be caused by a change of the position of the Fermi level, which is the same as for unmodified CdS, it may originate from the anodic shift of

FIGURE 13.4 Dependence of photovoltage (vs. NHE) on pH value of the methylviologen (MV²⁺) containing electrolyte. CdS (A), CdS-50/SiO₂ (B), CdS-30/SiO₂ (C), and CdS-12/SiO₂ (D).

SCHEME 13.8 Schematic description of improved charge separation in CdS-grafted ZnS.

the valence band edge, which should result in an acceleration of the oxidative IFET reaction. Since this energy band has predominantly sulfur character, the shift should increase the binding energy of the sulfur $2p$ electrons. In fact, values of 162.7 and 162.9 eV were measured for CdS and CdS-50/SiO₂, respectively.¹⁰⁷

A further improvement of photocatalytic activity may be accomplished by replacing the nonconductive silica by a semiconducting support. Grafting CdS onto ZnS affords CdS-17/ZnS having an about 40 times higher visible light activity in the reduction of carbon dioxide to formate than unsupported cadmium sulfide.¹¹⁰ This can be rationalized by assuming that an interparticle electron transfer from the valence band of zinc sulfide to CdS prevents electron–hole recombination (Scheme 13.8).

13.3 Photocatalysis Type A Reactions

13.3.1 Dealkylation, Cyclization, and Hydroalkylation

Induced by the early work of Bard et al. on the TiO₂-catalyzed photo-Kolbe reaction,⁴³ many papers appeared thereafter dealing with photocatalytic¹¹² organic reactions in the presence of colloidal or suspended semiconductor particles.³¹ They include *cis-trans* isomerizations,^{70,113–117} valence isomerizations,^{118,119} substitution and cycloaddition reactions,^{75,80,120–123} oxidations,^{124,125} and reductions.^{126–128} In almost all cases, well-known compounds were formed, which were not isolated but only identified by spectroscopic methods. The nature of products can be rationalized within the mechanistic scheme of semiconductor photocatalysis type A, which means at least one reduced and one oxidized compound are obtained (see Scheme 13.1). In most cases, it is the oxidative part of the reaction wherein the organic substrate is involved. This means that the reactivity of the initially formed radical cation determines the kind of products finally formed. Typical reactions of radical cations are deprotonation, bond cleavage, and electron transfer.^{129,130} An early example which illustrates two important mechanistic cases is the exhaustive photodealkylation of methylene blue and rhodamine B^{55,131,*} catalyzed by nonplatinized CdS (see Scheme 13.4). This mechanistic case is rather rare since in general light is absorbed by the semiconductor and the radical cation is generated in the oxidative primary step through IFET from the substrate to the reactive hole (h_r^+). In addition to deprotonation via C–H cleavage, radical cations may be transformed to the corresponding radicals also by C–C, C–Si, and other bond cleavages. The *intra-* or *intermolecular* consecutive reactions of these radicals usually determine the chemoselectivity of the overall reaction. Examples for intramolecular reactions are cyclizations of diamino dicarboxylic acids^{132,133} and the hydrazone **3**,¹³⁴ which both proceed via C–N coupling. The proposed mechanism for

* Here and in the following, the use of the chemical formula indicates that the semiconductor was present as a powder suspension.

SCHEME 13.9 Cyclization of hydrazone **3**. Deprotonation induced C–N bond formation. Note that two electron–hole pairs are necessary to produce one product molecule **4** ($2e^-/2h^+$ process).

the oxidative part of the latter reaction is summarized in Scheme 13.9, wherein the reductive part, most likely reduction of water, is omitted.

An example for an intermolecular consecutive reaction is the hydroalkylation of olefins.^{135,136} TiO_2 photocatalyzes the reaction of benzyltrimethylsilane (**5**) and maleic acid (**6**) to the hydroalkylation product **8** with dibenzyl (**7**) and 1,2-dibenzylsuccinic acid (**9**) as by-products (Scheme 13.10). It is proposed that in the reductive primary step **6** is reduced to the relatively stable radical anion $6^{\bullet-}$. The oxidatively formed radical cation $5^{+\bullet}$ undergoes a fast C–Si bond cleavage to Me_3Si^+ and PhCH_2^\bullet . Addition of the latter to **6** followed by proton-coupled reduction by $6^{\bullet-}$ or e_r^- affords **8**. Different from the cyclizations mentioned earlier, only one electron–hole pair is required to obtain one molecule of the product **8** ($1e^-/1h^+$ process).

The hydrazone cyclization and hydroalkylation reactions are rare examples of semiconductor photocatalysis conducted on a preparative scale, since the products were isolated in milligram amounts and not just identified in solution. As already mentioned in Section 13.2.4, photocorrosion of the semiconductor photocatalyst quite often prevents its use in preparative chemistry. This is very true for colloidal semiconductors; although the pseudo-homogeneous nature of their solutions allows classical mechanistic investigations, until now they were too labile to be used in preparative chemistry.^{108,137,138}

SCHEME 13.10 Hydroalkylation of maleic acid by benzyltrimethylsilane through C–Si bond cleavage of the intermediary radical cation followed by addition of the generated radical to maleic acid and final hydrogen abstraction.

In general, all the reactions mentioned earlier do not lead to novel products nor do they introduce novel aspects to organic synthesis. Different from this, the reactions discussed in the next two chapters produce new compounds on a gram-scale. The major part of them are atom-economic addition reactions, termed semiconductor photocatalysis type B.

13.3.2 Dehydrodimerization of Cyclic Enol or Allyl Ethers and Olefins

Irradiation of an aqueous 2,5-DHF suspension of ZnS ($E_{\text{bg}} = 3.6 \text{ eV}$, $\lambda \leq 345 \text{ nm}$) with UV light affords a few liters of hydrogen and gram-amounts of the hitherto unknown dehydrodimer **10** in isolated yields of 60% (Scheme 13.11).^{139–141} No reaction is observed in the absence of water and the initially evolved hydrogen gas contains about 90% of D_2 when D_2O is employed. Colloidal zinc sulfide or high-purity single crystals do not catalyze the reaction.¹⁰³ The use of platinized CdS ($E_{\text{bg}} = 4.2 \text{ eV}$, $\lambda \leq 520 \text{ nm}$) enables a reaction by visible light, but with a poorer yield.¹⁴⁰ Structure and statistical ratio of the three regioisomeric dehydrodimers suggest that the products are formed by dimerization of an intermediate dihydrofuryl radical. Hydrogen and dehydrodimer formation can be rationalized within the scheme for semiconductor photocatalysis type A as depicted in Schemes 13.1 and 13.11. In the reductive reaction step water is reduced to hydrogen (Equation 13.21), whereas in the oxidative part 2,5-DHF is oxidized to the dihydrofuryl radical and a proton (Equation 13.22). According to this, although water is reduced, it should not be consumed, since it is reformed as indicated by the sum of the two equations. In fact, even after production of 2–3 L of hydrogen, no water consumption could be measured. The net reaction can therefore be summarized according to Equation 13.23:

Further support stems from the observation that the initially observed D_2 content of 90% drops to 40% after evolution of 1 L of hydrogen, whereas the sum of HD and H_2 increased from 10% to 60%.¹⁴¹ From these results, it is obvious that the formation of D_2 from D_2O in “sacrificial” systems for water reduction is a necessary but not sufficient criterion for “permanent” water cleavage.* This result is of basic importance since in no system for “sacrificial” photochemical hydrogen production the consumption of water was ever proven.

SCHEME 13.11 Semiconductor photocatalyzed dehydrodimerization of 2,5-dihydrofuran. SC = ZnS, Pt/CdS. In the two other product isomers C–C bond formation occurred in the 3,3'- and 3,2'-positions ($2e^-/2h^+$ process).

* An often neglected aspect in many “sacrificial” systems of water splitting.

FIGURE 13.5 Structures of dehydrodimers of 3,4-dihydropyran, 3-methyl-2,5-dihydropyran, and cyclohexene.

Since the dehydrodimer **10** was not known before, this reaction is the first example for the preparation of a novel compound through semiconductor photocatalysis. The analogous products **11**, **12** are obtained from 3,4-dihydropyran (3,4-DHP), 3-methyl-2,3-dihydropyran (3-MeDHP), and cyclohexene in isolated yields of 30%–60% (Equation 13.23, Figure 13.5).⁹⁴ The saturated ether tetrahydrofuran is also dehydrodimerized while 1,4-dioxane does not react. In situ prepared zinc sulfide, which was independently investigated by Yanagida et al., photocatalyzes the same reactions but exhibits a slightly different chemoselectivity as indicated by the dehydrodimerization of 1,4-dioxane.^{142,143}

To unravel the detailed mechanism, substrate adsorption, quenching, inhibition, and kinetic studies were conducted for the ZnS-catalyzed photodehydrodimerization of 2,5-DHF.^{97,103} A plot of the amount of 2,5-DHF adsorbed (n_{eq}) against the residual concentration in solution (c_{eq}) exhibits saturation plateaus at $n_{\text{eq(max)}}$ of 2.8×10^{-3} and $65 \times 10^{-3} \text{ mol g}^{-1}$. The first plateau is due to formation of a mixed solvent–solute surface monolayer and the second corresponds to multilayer adsorption. Assuming that the formation of the monolayer can be described by competitive adsorption between water and 2,5-DHF, the data can be analyzed according to the Hiemenz model.^{144,145} In addition to an adsorption constant of $170 \pm 30 \text{ L mol}^{-1}$ the average area occupied by 2,5-DHF in the surface–solute monolayer is obtained as 10.2 \AA^2 . The latter value agrees well with 9.1 \AA^2 as calculated for 2,5-DHF adsorbed edge-on to the ZnS surface.* From the surface density of zinc sites ($11.4 \times 10^{-6} \text{ mol m}^{-2}$) of cubic zinc sulfide¹⁴⁶ and the specific surface area ($100\text{--}170 \text{ m}^2\text{g}^{-1}$) of the ZnS employed, one estimates that the surface concentration of 2,5-DHF in the saturated monolayer is in the range of $(1\text{--}2) \times 10^{-3} \text{ mol g}^{-1}$. This good agreement with the experimental value of $2.8 \times 10^{-3} \text{ mol g}^{-1}$ suggests that each zinc site is occupied by a 2,5-DHF molecule. The rather small downfield shift of 1.5 ppm as observed for the C(sp³) atoms of adsorbed 2,5-DHF by ¹³C NMR suggest that the oxygen atom does not directly interact with zinc sites but rather indirectly through hydrogen bonding to coordinated water.

To find out if emissive (e_{tr}^- , h_{tr}^+) and reactive (e_{r}^- , h_{r}^+) electron–hole pairs are identical or not, emission quenching and reaction inhibition studies were performed.¹⁰³ Addition of zinc or cadmium sulfate slightly increases or does not alter the emission intensity of an aqueous ZnS suspension respectively. 2,5-DHF has no significant influence. The two emission bands at 366 and 430 nm correspond to the transitions $h\nu_1$ and $h\nu_2$, respectively. Contrary to emission, the reaction is strongly inhibited when cadmium or zinc salts are added. This indicates that emitting and reacting surface sites are different. A Stern–Volmer plot of the reduced reaction rate as function of the initial inhibitor concentration affords a straight line only, when the concentration of adsorbed ions is employed (Figure 13.6). From the

* Estimated according to $3.8 \text{ \AA} \times 2.4 \text{ \AA}$.

FIGURE 13.6 Stern-Volmer plot of the ZnS-photocatalyzed dehydrodimerization of 2,5-dihydrofuran.

corresponding slopes, Stern-Volmer constants of $13 \times 10^3 \text{ M}^{-1}$ and $50 \times 10^3 \text{ M}^{-1}$ are calculated for Zn^{2+} and Cd^{2+} , respectively.^{24,147*} Copper(II) ions exert only a very weak inhibition.

Inhibition by Cd^{2+} proceeds via competitive IFET (Equation 13.24), since even at the very low concentration of $3.9 \times 10^{-6} \text{ mol g}^{-1}$ formation of elemental cadmium is observable; complete inhibition occurs at $6 \times 10^{-4} \text{ mol g}^{-1}$:

This differs significantly from the effect of zinc ions in which the expected elemental zinc^{101,102} could not be detected, even at the high concentration of 0.8 mol g^{-1} . From this, one can conclude that zinc ions either prevent formation of the reactive electron-hole pair or efficiently promote its radiationless deactivation (Scheme 13.12).

SCHEME 13.12 Simplified mechanistic scheme of the ZnS-photocatalyzed dehydrodimerization. RH = unsaturated ether, olefin.

* Although the lifetime of the reactive electron-hole pair is not known, the reasonable estimate of 10^{-6} – 10^{-9} s leads to an electron transfer rate constant between 10^{10} and $10^{13} \text{ M}^{-1}\text{s}^{-1}$. In general, electron transfer reactions at the semiconductor-liquid interface are very fast.

From detailed inhibition studies with various metal ions, it follows that Fe^{2+} and Ni^{2+} accelerate the reaction up to a concentration of about $0.7 \times 10^{-3} \text{ M}$, but inhibit the reaction at concentrations above 2×10^{-3} and $6 \times 10^{-3} \text{ M}$, respectively.⁹⁷ In the case of Mn^{2+} no maximum is seen, but a plateau starts forming at about $1 \times 10^{-3} \text{ M}$. At a given surface concentration of these ions ($n_{\text{eq}} = 3 \times 10^{-5} \text{ mol g}^{-1}$), no simple relation is observed with the reduction potentials of the metal ions. However, the reaction rate increases approximately linearly with the exchange current density of hydrogen evolution at the corresponding metal electrode. This strongly suggests that water reduction at the photoexcited $\text{ZnS}/\text{M}_{\text{ad}}^{2+}$ -surface occurs at small metal islands generated by photoreduction.

From these results, the primary events at the ZnS surface can be summarized as schematically depicted in Scheme 13.12. The light generated electron–hole pair has a lifetime of 0.1–20 ns and either recombines through radiative or nonradiative processes or is trapped at emitting (e_{tr}^{-} , h_{tr}^{+}) or reacting surface (e_{r}^{-} , h_{r}^{+}) sites. Whereas the former are detected by their emission at 440 nm, the latter could not be observed directly but their existence is evidenced through the inhibition experiments with the metal ions. The reduction of water most likely is located at surface states generated by zinc metal islands as also postulated for the photooxidation of alcohols at colloidal zinc sulfide.¹⁴⁸ For the formation of the 2,5-dihydrofuryl radical in the oxidative part of the reaction, three pathways may be considered. Firstly, hydrogen abstraction by a surface sulfur radical. Although such radicals have been detected at zinc sulfides,^{74,113,149,150} this reaction path is rather unlikely since THF is also dehydrodimerized but does not undergo H-abstraction with sulfur-centered radicals in homogeneous solution.¹⁵¹ Secondly, a stepwise formation through an initially formed radical cation takes place followed by deprotonation. And thirdly, a concerted process is observed where IFET is coupled to deprotonation, as indicated in Scheme 13.12. Although a final decision between the two latter processes is not possible at present, all experimental evidence is in favor of the concerted pathway.

Although the position of the redox potential of the reactive hole is not known, it can be estimated to be in the range of 1.6–2.0 V by considering that the value of the valence band edge reported for crystals (1.8 V) may be shifted through substrate adsorption as known for other semiconductors.^{152–155} From the oxidation potential of 2,5-DHF of 2.6 V, it follows that the oxidation to the radical cation is endergonic by at least 0.6 eV. Accordingly, there is no simple relation between apparent product quantum yield and redox potential when various substrates are compared. On the other hand, a similar estimation for the concerted process (Equation 13.25) reveals that the reaction is exergonic by at least 0.9 eV.^{165,*}

Since the driving force of this reaction is the difference between the free enthalpy of C–H bond homolysis and the potential of the hydrogen electrode, the former value should be decisive when comparing apparent quantum yields of various substrates. Figure 13.7 displays the relation between quantum yield and calculated bond dissociation energy of the corresponding C–H bond.¹⁰³ The expected increase with decreasing bond strength favors the concerted oxidation pathway. The deviation of 3-MeDHP most likely arises from steric hindrance of the radical C–C coupling step by the adjacent methyl group.

Once formed, the dihydrofuryl radicals may undergo a variety of reactions as known from homogeneous chemistry including disproportionation, addition to double bonds, electron transfer, and dimerization. Surprisingly, the latter pathway is followed to about 90% as indicated by the complete material balance.¹⁴¹ It is therefore likely that C–C coupling occurs between radicals within the water–2,5-DHF surface layer. This is corroborated by the quadratic dependence of the initial rate on the amount of

* Calculated by using $E_0(\text{H}^+/\text{H}) = -2.40 \text{ V}(\text{H}_2\text{O})$ ¹⁵⁷ and a bond dissociation energy of 3.22 eV¹⁰⁰; these were converted to the $\Delta G(\text{H}_2\text{O})$ values by subtracting 0.1 eV for the solvent contribution.¹⁵⁷ The same argument was used to explain the photooxidation of alcohols by ZnS¹⁵⁰.

FIGURE 13.7 ZnS-photocatalyzed dehydrodimerization of 2,5-DHF. Dependence of apparent product quantum yield on the calculated bond dissociation energy of the allylic C–H bond.

adsorbed 2,5-DHF. This dependence corresponds to a heterogeneous catalytic dimerization by a modified Langmuir–Hinshelwood mechanism affording easily desorbable products.¹⁵⁷ It further suggests that at early reaction stages the concentration of adsorbed radicals increases linearly with the bulk concentration of 2,5-DHF. The latter relation breaks down as the reaction progresses, since the consumption of 2,5-DHF is faster than its adsorption from solution. Accordingly, the instantaneous rate decreases stronger with time for lower starting concentrations than for higher and finally becomes diffusion controlled.⁹⁷ C–C coupling between radicals adsorbed in the water–2,5-DHF surface layer is further supported by competition experiments with THF. Although the unsaturated ether reacts only ten times faster than the saturated one, no THF dehydrodimers or cross-products are detected when THF is present in 10-fold excess over 2,5-DHF. Only at a 500-fold higher concentration the expected products are observed.

In summary, one can conclude that the formation of H₂ and the dehydrodimer occurs via subsequent adsorption of two photons (2e⁻/2h⁺-process). The mutual adsorbed hydrogen atom and dihydrofuryl radical generated by the first photon must have lifetimes long enough to wait for the arrival of the second photon. This requirement is easily fulfilled since at a micrometer-sized ZnS particle the time interval between two successive photon absorptions can be estimated to be in range of 20 ps, much shorter than the lifetime of radicals and radical cations, which are in the range of at least nanoseconds. But the question arises why the C–C homocoupling between two radicals is so highly favored over C–H heterocoupling with an adsorbed hydrogen atom to re-form 2,5-DHF.^{141,*} One possibility is that the first electron does not produce an adsorbed hydrogen atom, but is stored at the metallic zinc center and water is subsequently reduced in a two-electron step. Or, the adsorbed hydrogen atom does not undergo coupling to the dihydrofuryl radical because of unknown kinetic barriers. Therefore it seemed worthwhile to replace water by an organic acceptor that could produce a more stable one-electron reduction intermediate, perhaps capable of undergoing the postulated heterocoupling with the one-electron oxidation intermediate. The following chapter illustrates that this concept led to the catalysis of photoaddition reactions, classified as semiconductor photocatalysis type B.

* It is noted that deuterium is not incorporated into unreacted 2,5-DHF and dehydrodimers when D₂O is employed.

13.4 Semiconductor Photocatalysis Type B

13.4.1 Linear Addition of Cyclic Enol/Allyl Ethers and Olefins to 1,2-Diazenes

Upon addition of azobenzene to a running ZnS-catalyzed photodehydrodimerization experiment of 2,5-DHF, hydrogen evolution is completely inhibited in favor of formation of the novel allylhydrazine **13c**, a linear addition product of 2,5-DHF to azobenzene; small amounts of hydrazobenzene (**14**) are formed as a by-product (Scheme 13.13).^{137,138} When all the azobenzene is consumed and some excess 2,5-DHF is still present, hydrogen evolution starts again. Replacing ZnS by CdS or silica-supported CdS (CdS/SiO₂),¹⁵⁸ allows to conduct the reaction with visible light; a simple tungsten-halogen lamp can be used instead of the high-pressure mercury lamp. When colloidal CdS¹⁵⁹ is employed in the system 3,4-DHP/1,2-diphenyldiazene/MeOH, no photoaddition but efficient photocorrosion occurs. Scheme 13.13 summarizes the novel allylhydrazines **13a–f** prepared on a gram scale by this simple route employing methanol as the solvent.^{137,138} Due to the poor crystallization properties, isolated yields are only in the range of 10%–40% whereas HPLC yields are about twice larger. Structural assignments are based on an x-ray structural analysis of **13b** and on standard spectroscopic data. Dynamic NMR spectra of **13b** reveal that rotation around the N–N bond is hindered; the corresponding free activation enthalpy amounts to 14 kcal mol^{–1}.

From a few examples of limited synthetic utility it is known that the same reaction type may occur in homogeneous solution when either the 1,2-diazene^{160–162} or the olefin^{163–165} is substituted by electron-withdrawing groups. Some other allylhydrazines have been prepared by more conventional thermal procedures.¹⁶⁶

The photoaddition exhibits a significant solvent dependence. No reaction occurs in dry *n*-hexane or THF, but upon addition of water or methanol the reaction is as fast as in pure methanol. From the discussion at the end of Section 13.3.2 and the experimental results presented earlier, a simplified reaction scheme can be constructed (Scheme 13.14):

Since the presence of the diazene completely inhibits hydrogen evolution and the reaction proceeds only in protic solvents or in the presence of water, the reductive IFET is formulated as a proton-coupled reduction of the diazene to a hydrazyl radical (Equation 13.26):

Hydrazyl radicals derived from 1,2 diaryl- and 1,2-dialkyldiazenes have been postulated¹⁶⁷ and identified in homogeneous solution by ESR.¹⁶⁸ The observation that the product **13a**, obtained from

SCHEME 13.13 Synthesis of allyl hydrazines through addition of cyclic allyl/enol ethers and olefins to 1,2-diazenes photocatalyzed by ZnS or CdS suspended in methanol.

SCHEME 13.14 Simplified mechanistic scheme for the CdS or ZnS photocatalyzed addition of cyclic unsaturated ethers or olefins to 1,2-diazenes ($1 e^-/1 h^+$ process). See also Scheme 13.13.

1-*tert*-butyl-2-phenyldiazene, consists of only one isomer is in agreement with the expectation that the hydrazyl radical should be more stable when the unpaired electron is localized rather on the PhN than on the *t*BuN group. The oxidative IFET is assumed to proceed as described for the photodehydrodimerization. Heterocoupling of the hydrazyl and allyl radicals affords the allylhydrazine. Thus, formation of the addition product is a $1e^-/1h^+$ process, whereas the by-products are formed via a $2e^-/2h^+$ process, irrespective whether the hydrazobenzene derivative **14** is formed by subsequent reduction or disproportionation of the hydrazyl radical (Equations 13.27 and 13.28). The energetic relations between band positions and redox potentials are summarized in Figure 13.8:

Formation of the hydrazobenzene product is strongly favored when platinized zinc or cadmium sulfide is used as the photocatalyst. In both cases the rate decreases considerably and hydrazobenzene becomes the major product. It is known that the presence of platinum favors multielectron processes.²⁵

Substrate adsorption studies as conducted with ZnS in aqueous solution were performed also with CdS, CdS/SiO₂, and SiO₂ in methanol, the solvent employed in the photoaddition reaction.¹⁵⁸

FIGURE 13.8 Metal sulfide band edge and substrate redox potential positions. Single crystal (a), powder (b), RH = 2,5-DHF (c) [166].

From ^{13}C NMR spectra of 2,5-DHF adsorbed from the gas phase onto the dry powders it is concluded that 2,5-DHF is adsorbed parallel to the surface. In the case of CdS/SiO_2 the data resemble those of unmodified SiO_2 and therefore suggest that adsorption of 2,5-DHF occurs primarily at the silica surface. In agreement with this conclusion, SiO_2 and CdS/SiO_2 afford the same adsorption constant of 30 M^{-1} , which is about 50% larger than for pristine CdS (vide infra). From the maximum surface concentration of $0.4 \times 10^{-3}\text{ mol g}^{-1}$ found for 2,5-DHF and the maximum number of $1.54 \times 10^{-3}\text{ mol g}^{-1}$ calculated for the Cd^{2+} surface in cubic CdS ,¹⁶⁹ it is estimated that 2,5-DHF adsorbs at about every fourth Cd^{2+} center, in agreement with a parallel adsorption. However, the presence of also perpendicular adsorption cannot be excluded. Contrary to this, when 2,5-DHF is adsorbed onto ZnS from aqueous suspension, it occupies each Zn^{2+} site in a perpendicular mode and the maximum surface concentration matches the calculated molecular area.¹⁰³ This difference can be rationalized by comparing the polarities of the two sulfides with those of 2,5-DHF and the solvents employed. Since the surface polarity parameter E_{T}^{N} of CdS (0.68 ± 0.06) is comparable with the value of methanol ($E_{\text{T}}^{\text{N}} = 0.762$),¹⁷⁰ but is much higher than that of 2,5-DHF ($E_{\text{T}}^{\text{N}} = 0.366$),^{171,*} displacement of MeOH_{ad} by 2,5-DHF should be disfavored. Contrary to that, the highly polar solvent water ($E_{\text{T}}^{\text{N}} = 1.0$)¹⁷⁰ is displaced almost completely from the less polar ZnS surface ($E_{\text{T}}^{\text{N}} = 0.57$)⁹⁷ by the less polar 2,5-DHF. This explanation is corroborated by the data obtained for 2,5-DHF when it is adsorbed onto CdS from an aqueous solution. In this case, comparison of the maximum surface concentration of $2.1 \times 10^{-3}\text{ mol g}^{-1}$ with the calculated maximum number of Cd^{2+} surface sites reveals that about each Cd^{2+} center is occupied by 2,5-DHF. The average area occupied by 2,5-DHF in the surface-solute monolayer is obtained as $7 \pm 1\text{ \AA}^2$. It matches well with the area of 9 \AA^2 calculated for a perpendicular adsorbed molecule. The change to the more polar solvent water enables an almost fivefold higher surface coverage of CdS . For CdS/SiO_2 the maximum surface concentration of 2,5-DHF ($1.6 \times 10^{-3}\text{ mol g}^{-1}$) is about the sum of the values for CdS-A ($0.4 \times 10^{-3}\text{ mol g}^{-1}$) and SiO_2 .

The observation that the adsorption constants of 2,5-DHF onto SiO_2 and CdS/SiO_2 are equal suggests predominant adsorption on the SiO_2 support in the latter case. The better adsorption onto CdS/SiO_2 ($K_{\text{ad}} = 30 \pm 1\text{ M}^{-1}$) as compared to CdS-A ($K_{\text{ad}} = 18 \pm 2\text{ M}^{-1}$) is connected with a faster reaction. Since the amount of azobenzene adsorbed is the same for both photocatalysts, it is likely that the higher 2,5-DHF surface concentration induced by SiO_2 increases also the amount of 2,5-dihydrofuryl radicals adsorbed at CdS and therefore accelerates C–N coupling with the PhN-NHPh radicals.

In comparison to 2,5-DHF, the maximum surface concentration $n_{\text{eq(max)}}$ for azobenzene of about $10^{-5}\text{ mol g}^{-1}$ is two orders of magnitude lower, whereas the adsorption constants are much higher and do not depend on the nature of the adsorbent. Comparison of the σ° -values with the area covered by a flat, unsolvated molecule (52 \AA^2),[†] reveals that σ° for CdS , CdS/SiO_2 , and SiO_2 is 52, 85, and 145 times higher than expected. It is estimated that in the case of CdS only every 220th Cd^{2+} site interacts with an azobenzene molecule. Depending on the adsorbent, only 0.7%–2% of the surface area is covered, which suggests that the more polar methanol ($\mu = 1.7\text{ D}$) efficiently competes with the less polar *trans*-azobenzene[‡] ($\mu_{\text{trans}} \cong 0\text{ D}$) for adsorption sites at the relatively polar CdS surface. Together with the independence of the adsorption constant on the nature of the adsorbent, these results suggest that adsorption occurs through interaction with Brønsted acid sites.^{158,172} In this case the independence of the adsorption constant on the adsorbent can be rationalized since according to literature CdS and SiO_2 have similar pK_{s} values (6.1, 9.0¹⁷³ and 6–8,¹⁷⁴ respectively) and the employed photocatalysts CdS or CdS/SiO_2 and SiO_2 have two surface centers of similar pH values.¹⁷⁵

The considerations outlined earlier are substantiated further by the σ° values as obtained from Hiemenz plots. The area covered by a 2,5-DHF molecule in the saturated surface-solute-monolayer is found to be

* From comparison with the dipole moments of THF, 2,5-DHF and furan (1.63, 1.59 and 0.66 D, respectively) one would expect, however, that the E_{T}^{N} value of 2,5-DHF should be in the range of 0.164 to 0.27, corresponding to furan and THF, respectively.

† Estimated from a molecular model as $10.8\text{ \AA} \times 4.8\text{ \AA}$.

‡ Since in the dark adsorption experiments light could not be completely excluded, *cis*-azobenzene was present in about 1%.

50 ± 5 , 35 ± 2 , and $20 \pm 1 \text{ \AA}^2$ for CdS-A, SiO₂, and CdS/SiO₂, respectively, and differs not too much from the area of 21 \AA^2 as calculated for an unsolvated molecule adsorbed parallel to the surface.* This qualitative agreement with the conclusions drawn from the maximum numbers of metal ion sites as well as the ¹³C NMR data strongly suggests that 2,5-DHF adsorbs at surface [OH] or [SH] groups via hydrogen bonding.

Apparent quantum yields were measured at 366 nm, the wavelength at which light absorption by the diazene is minimized.¹³⁸ In the system, CdS/R³H/1,2-diphenyldiazene/MeOH Φ_{app} of allylhydrazine formation increases from 0.02 (2,5-DHF) over 0.03 (cyclohexene) and 0.04 (3,4-DHP) to 0.05 (2,3-DHF). As also observed for the ZnS-catalyzed photodehydrodimerization, there is no simple relation with the oxidation potential of the donor, which is 2.6 V for 2,5-DHF and cyclohexene, and 1.9 and 2.0 V for 3,4-DHP and 2,3-DHF, respectively. Although 3,4-DHP as compared to 2,5-DHF is more readily oxidized than 2,5-DHF by 0.7 V, its quantum yield is only twice as large. In contrast to these rather weak effects, lowering of the reduction potential of the diazene causes a strong increase of the *relative* quantum yield[†] of diazene disappearance. For cyclohexene addition in the series 1,2-bis(*p*-tolyl)diazene, 1,2-diphenyldiazene and 1,2-bis(*p*-chlorophenyl)diazene, E_{red} varies from -0.82 to -0.75 and -0.66 V ¹⁷⁶ and Φ_{rel} increases from 0.5 over 1.0 to 5.0, respectively.

Thus, although the *p*-chloro derivative is easily reduced than the *p*-methyl analogue by only 0.16 V, the quantum yield is ten times larger. No photoaddition or reduction is observed in the case of 2,3-diazabicyclo[2.2.1]hept-2-ene. It is known that aliphatic diazenes are much more difficult to reduce than aromatic ones.¹⁷⁷

The postulated C–N heterocoupling requires diffusion of the two radicals either in the solvent–solute surface layer or in the bulk solution. In both cases one expects that the reaction rate should decrease with increasing solvent viscosity. To achieve the latter, the CdS/SiO₂-catalyzed photoaddition of 2,5-DHF to azobenzene was conducted at pressures ranging from 0.1 to 120 MPa.¹⁵⁹ Both the formation rates of the addition and reduction products **13c** and **14** ($R^1 = R^2 = \text{Ph}$) decrease with increasing pressure (Figure 13.9). From a plot of $\ln(\text{rate})$ vs. pressure, activation volumes ΔV^\ddagger are obtained as $+17.4 \pm 3.4$ and $+15.8 \pm 2.3 \text{ cm}^3 \text{ mol}^{-1}$, for **13c** and **14**, respectively. However, since with increasing pressure also the dielectric constant increases, the observed effects may originate from the change of this property.^{173–181} In order to differentiate between these two possibilities, the rates were measured in a series of alcohols for which viscosity and dielectric constant change in an opposite fashion. Whereas the rates again decrease with

FIGURE 13.9 Dependence of the formation rates of **13c** and **14** on applied pressure.

* Estimated from a molecular model as $4.6 \text{ \AA} \times 4.5 \text{ \AA}$.

† The apparent quantum yield for 1,2-diphenyldiazene was set to 1.0.

increasing viscosity, they increase when plotted as function of increasing dielectric constant. This indicates that the rate decrease at higher pressure is a viscosity effect.

It is unlikely that the activation volume is connected with substrate adsorption and product desorption¹⁸² or with the interfacial electron transfer steps. Usually interfacial collision rates depend on molecular mass but not on diffusion rates.¹⁸³ Therefore, the activation volume measured for the formation of **13c** may stem from the diffusion of the intermediate radicals to each other or from the subsequent C–N coupling step itself. The latter case can be excluded since bond formation between neutral organic species in homogeneous solution in general has a negative activation volume.^{184–187} The only exception is radical recombination in the termination step of polymerizations.^{188,189} These reactions possess ΔV^\ddagger values in the range of +13 to +25 cm³ mol^{−1}, which are composed of the large and positive contribution of diffusion and the small and negative part of radical C–C coupling. Hence, the activation volume found for **13c** most likely originates primarily from diffusion of the intermediate radicals to each other and only to a minor part from C–N coupling and therefore should resemble the activation volume for the viscous flow of methanol. The fact that the latter value of +8 cm³ mol^{−1}¹⁸⁸ is significantly smaller suggests that the radicals do not diffuse in the bulk homogeneous solution but in a solvent–solute–surface layer. This should result in a higher viscosity and consequently the activation volume should become more positive. In accordance with this interpretation are also the small activation energies of 2.8 ± 0.3 (**13c**) and 2.5 ± 0.2 kcal mol^{−1} (**14**).

Since the same activation parameters as for **13c** were also found for the formation of the reduction product **14**, the disproportionation pathway (Equation 13.27), which involves radical diffusion, is favored over the secondary reduction step (Equation 13.28). However, the latter may be partly involved as suggested by the slightly smaller pressure effect as compared to **13c**.

The conclusion that changes in solvent viscosity are responsible for the observed pressure and temperature effects is further corroborated by the same dependence of the product ratio **13c**:**14**. Irrespective of whether the viscosity is calculated from the pressure or temperature experiments, a plot of the product ratio vs. viscosity affords two straight lines with slopes identical within experimental error. When the different alcohols were used to change the viscosity, the product ratio also decreased with increasing viscosity.

13.4.2 Linear Addition of Cyclic Enol/Allyl Ethers and Olefins to Imines

According to the proposed mechanism for this novel photoaddition reaction, other substrates capable of forming radicals upon CdS-photoinduced one-electron oxidation or reduction should undergo similar C–C coupling. Replacing the 1,2-diazene by the trisubstituted imine **15** indeed affords the new homoallyl amines **16a–g** in isolated yields of 30%–75% (Scheme 13.15).¹⁹⁰

SCHEME 13.15 Synthesis of homoallyl amines through addition of cyclic allyl/enol ethers and olefins to trisubstituted imines photocatalyzed by CdS suspended in methanol.

(a) Isolated yield in %.

SCHEME 13.16 CdS photocatalyzed addition of cyclic allyl/enol ethers and olefins to disubstituted imines photocatalyzed by CdS suspended in methanol. Imine hydrodimers **19** are formed as by-products.

The structure of the new compounds is confirmed by single crystal x-ray analyses of **16a**, **c**, and **d**, and by comparative NMR data in the case of the other products.

When a disubstituted imine (**17a–d**) is employed instead of the trisubstituted one, in addition to the homoallylamine (**18**) also the hydrodimer (**19**) of the imine, that is, the dimer of the postulated α -aminobenzyl radical, is isolated (Schemes 13.16 and 13.17).^{191,192} The observation that the hydrodimer is produced only from the disubstituted but not from the trisubstituted imine parallels the electrochemical reduction, which affords hydrodimers from aldimines¹⁹³ but not from ketimines.^{193,194}

Thus, product formation can be rationalized by assuming that the allylic radical generated in the oxidative IFET, as discussed earlier, undergoes C–C heterocoupling with the α -aminodiphenylmethyl radical produced according to Equation 13.29. When CdS is alkylated through the reaction with 3-bromopropyltrimethoxysilane, the reaction is completely inhibited. However, it occurs again when the imine is substituted by its iminium salt. This indicates that the surface OH and SH groups of pristine cadmium sulfide photocatalyst protonate the imine to render its redox potential more positive.¹⁹⁵

SCHEME 13.17 Simplified mechanistic scheme for the CdS photocatalyzed addition of cyclopentene to imines.

SCHEME 13.18 Diastereoselectivity of C–C coupling. The menthylester affords the C2(R)C1(S), the endofenchylester leads to the C2(R)C1(R) stereoisomer.

In no case, a product arising from C–N heterocoupling could be observed. Thus, different from mutual thermal routes, which usually involve the use of organometallic reagents,^{196–198} the reaction is regioselective and much easier to perform.

To obtain information on the stereochemistry of the radical C–C coupling, chiral imines were employed in addition reactions with α -pinene (Scheme 13.18). With the menthyliminoester diastereoselective formation of the C2(R)C1(S) isomer occurs, whereas the endofenchylester leads to the C2(R)C1(S) diastereomer suggesting a stereospecific *si*- and *re*-attack of the aminobenzyl radical at the allyl radical, respectively.

As observed for the adsorption of 2,5-DHF also the imine **17a**, the adsorption isotherm indicates the presence of mono- and multilayer adsorption. From the former a maximum surface concentration of $20 \times 10^{-7} \text{ mol g}^{-1}$ can be estimated. Application of the Hiemenz model on the methanol-imine surface monolayer leads to an adsorption constant of $4400 \pm 950 \text{ M}^{-1}$ and a σ^0 value of 4000 \AA^2 . This is far too large as indicated by comparison with 50 \AA^2 ($14 \times 3.5 \text{ \AA}$) estimated for a flat unsolvated molecule. This suggests that only 1%–2% of the surface is covered by **17a** in competition with the solvent. The results resemble those obtained for the adsorption of azobenzene. Assuming a size of 8 \AA^2 for methanol, one arrives at the conclusion that methanol is present in a 500-fold excess over the imine in the methanol-imine surface monolayer. Therefore it is rational that **17c** does not influence the photocurrent of a CdS electrode whereas methanol induces current doubling.¹⁹⁹ Although these numbers are only rough estimates, they are not unexpected since methanol should adsorb much stronger than **17a** onto the hydrous CdS surface.²⁰⁰

Control experiments with **17a** showed that in the absence of olefins hydrodimers were also formed but the reaction rate was decreased by about 90%. Whereas the reductive reaction step can proceed as depicted in Scheme 13.17, the solvent must be involved in the oxidative step since no significant oxidative photocorrosion occurs. Accordingly, irradiation of CdS in a solution of **17a** in different alcohols transforms the imine at different rates and the corresponding addition products **20a–e** and hydrodimers **21a–e** are isolated (Scheme 13.19).

Except for methanol and 2-propanol the products are racemic diastereomeric mixtures isolated in low yields (5%–20%); they are often mixed with the two-electron reduction product *N*-4-chlorobenzyl-4-chloroaniline. The major product in all reactions is the hydrodimer **21**, obtained in yields of 10%

SCHEME 13.19 CdS-photocatalyzed addition of alcohols to the Schiff base **17a**.

(MeOH), 28% (BuOH), 29% (PrOH), 42% (EtOH), and 60% (*i*PrOH). The structure of **20** indicates that in all cases the α -CH bond of the alcohol is added to the imine in agreement with the preferred formation of α -hydroxyalkyl radicals from oxidation of alcohols.^{201,202} In the case of *i*PrOH, involvement of the intermediate hydroxyalkyl radical was corroborated through detection of its disproportionation product acetone. These results show that the solvent can be directly involved in the oxidative step. Formation of hydrodimers in the absence of olefins thus can be explained by the oxidation of alcohols. It is noted that in the presence of olefins, no alcohol addition products could be detected by HPLC analysis, although methanol is present in a 500-fold molar excess.

Increasing the light intensity results in a linear increase of the reaction rate. Above an incident intensity of about 10^{18} quanta s^{-1} a saturation effect is observed. This is in accord with other photoreactions catalyzed by semiconductor powders.^{68,70} Noteworthy, the product ratio of 0.9 observed for **18a:19a** is not influenced by changing the light intensity. This suggests that the rates of aminobenzyl radical dimerization and addition to the allyl radical exhibit the same dependence on the concentration of the light-generated electron-hole pairs.¹⁹²

The reaction rate increases approximately linearly on CdS concentration and reaches a plateau at about 3 g L^{-1} . Surprisingly, in the same concentration range the ratio of addition to hydrodimer product (**18a:19a**) decreases from 2 to about 1. In the same direction the surface concentration of the intermediate radicals should decrease although the ratio of α -aminobenzyl to cyclopentenyl radical concentration should not change. Therefore the product ratio is expected to stay constant. However, a lower concentration of the radicals increases their lifetime, assuming that they undergo only second-order decay reactions. This effect should favor hydrodimerization, which is a $2e^-/2h^+$ process and therefore requires that a second radical pair is generated during the lifetime of the first one. Furthermore, one can make the plausible assumption that there is still some weak interaction within a reactive electron-hole pair and therefore the distance between the charges in a pair should be smaller than the distance between neighboring pairs. This means that the radical homocoupling most likely requires a longer diffusion path than heterocoupling. Accordingly, a longer radical lifetime should also enable a more efficient diffusion and therefore additionally favor the hydrodimer formation.

Exploring the general applicability of the olefin-imine addition reaction, the N-aryl substituent in the imine **15** ($X=CN$) was replaced by an N-benzoyl group, which may be easily converted to an amino group. The resulting unsaturated amino acids may be of pharmaceutical relevance.^{203,204} Surprisingly, in the presence of CdS- or silica-supported CdS, the addition reactions with cyclopentene and cyclohexene were completely inhibited in favor of a novel thermal transhydrocyanation of the imine component affording novel malononitriles **6** in isolated yields of 40%–50%.²⁰⁵ However, in the presence of zinc sulfide-supported cadmium sulfide (CdS/ZnS) this dark reaction was completely inhibited in favor of the desired addition products **23** (65%–85% isolated yield). Unexpectedly, both the compounds **23** and **26** were unknown in the literature (Scheme 13.20).

SCHEME 13.20 Support-controlled chemoselectivity in the imine/olefin system.

To obtain information on the lifetime of the photogenerated charges, time resolved photo-electromotive force measurements were performed on various samples embedded in a polymer matrix.^{206,207} A fast decay process observed after excitation at $\lambda = 337$ nm in the time range of 0–50 μs is due to surface charge recombination. A positive voltage indicates n-type behavior as observed for all samples containing CdS. Different from this, ZnS possesses p-type character due to the negative voltage, which is still growing in the observed time range. Thus, the supported materials constitute a type of photochemical diode since they consist of the combination n-CdS/p-ZnS. The n/p-character of these aggregates is a significant difference to previously reported “coupled semiconductors” employed in oxidative photodegradation reactions.^{208,209} The charge carrier lifetime τ as obtained from the reciprocal decay constant k_1 increases from $\sim 3 \mu\text{s}$ in CdS to $\sim 4 \mu\text{s}$ and $\sim 5 \mu\text{s}$ in CdS-36/ZnS and CdS-13/ZnS containing 36 wt% and 13 wt% of CdS. This slower charge recombination can be rationalized by assuming an interparticle electron transfer at the CdS–ZnS interface as depicted schematically in Scheme 13.21. According to this, the n-CdS/p-ZnS photocatalyst in principle mimics the primary reactions of natural photosystem wherein light absorption by two components, photosystem I and photosystem II, is followed by charge separation and interfacial reduction and oxidation.

SCHEME 13.21 Photoinduced charge separation facilitated by interparticle charge transfer. The band edge positions for ZnS²¹² and CdS¹⁹⁵ refer to aqueous solutions at pH = 7 vs. NHE.

The problems inherent in the understanding of the factors determining the rate of a semiconductor-photocatalyzed reaction are nicely reflected when various *p*-substituted imines are compared. Although one might expect that a higher driving force of imine reduction (Equation 13.29) should increase also the addition rate constant, this is not the case.²¹⁰ Thus, whereas the reduction potential of the *p*-chlorophenyl substituted imine **22c** is 150 mV more positive than that of the bromo derivative **22d**, the rate constants do not differ significantly. Accordingly, the reduction potential does not influence the IFET reaction (see Equation 13.11) in a systematic fashion. Assuming then that rather the C–C coupling reaction is the rate-determining factor, the disturbance of the delocalized aromatic system as a function of the *para*-substituent was considered. Assuming that the basic conformational properties of **22a–f** are preserved also in the corresponding benzyl radicals one expects that a larger torsion angle $C_{\text{Imin}}-N_{\text{Imin}}-C_{\text{Carbonyl}}-C_{\text{Ph}}$ should indicate a lower stability due to a lower degree of electron delocalization. In fact, a steady increase of rate with increasing angle is observed. This can be rationalized by noting that less delocalization implies higher electron localization at the imine carbon atom and therefore a faster C–C coupling, resulting in a larger efficiency of product formation η_p (see Equation 13.12). Only the fluoro derivative **22b** does not follow this correlation, suggesting that radical and imine conformations may be too different.²¹⁰

In order to find out if the dependence of rate on the *para*-substituent of imines **22** may be better described by a parameter reflecting both thermodynamic and kinetic properties, the data were analyzed by application of the Hammett relation (Equation 13.30). In this equation the parameter σ is a constant for a given substituent X in the *p*-XC₆H₄ group of the imine. The value of ρ depends on the specific reaction. Generally, positive ρ -values indicate that enhanced electron-withdrawing properties of the substituents X increase the reaction rate:

$$\log(k_x/k_H) = \rho\sigma \quad (13.30)$$

A corresponding plot of the left term of Equation 13.30 vs. the σ -parameters reveals a linear relationship (Figure 13.10). Once more the fluorophenyl imine **22b** does not follow the general trend, as already observed when considering the imine distortion angle. The positive ρ -values of $\rho = 1.18$ and $\rho = 1.44$ for cyclopentene and cyclohexene, respectively, suggest a nucleophilic attack of the allyl radical at the α -aminobenzyl radical.

FIGURE 13.10 Hammett plot for the addition of cyclopentene to **22a–f**.

13.5 Summary

The unique charge-separating properties of the semiconductor–liquid interface enable micrometer aggregates of nanoscaled zinc and cadmium sulfide crystallites to act as efficient electron transfer photocatalysts for novel organic syntheses. Grafting of cadmium sulfide onto insulating silica or semiconducting zinc sulfide improves the photocatalytic activity through interparticle electronic interactions. In general reduced and oxidized products are obtained (semiconductor photocatalysis type A), in complete analogy with electrochemical syntheses. An example is the dehydrodimerization of unsaturated ethers in aqueous solution producing stoichiometric amounts of hydrogen. Although the latter is generated by reduction of water, it is not consumed but reformed in a subsequent reaction step as indicated by experiments in D₂O. The observed formation of D₂, therefore, is not a proof for hydrogen production from water as generally assumed in the literature for “sacrificial hydrogen production.” In a few cases, the semiconductor photocatalyzes a linear addition reaction between two unsaturated substrates affording one single product (semiconductor photocatalysis type B), a reaction type not known in classical electrochemistry. Typical examples are the addition of olefins or unsaturated ethers to 1,2-diazenes or imines. In both photocatalysis types the semiconductor action is at least bifunctional. It enables a proper assembling of the substrates through adsorption and catalyzes photoinduced interfacial electron transfer to and from substrates. The resulting primary redox products are radicals that may undergo regioselective C–C and C–N coupling to stable products in the case of class B reactions. These reactions are easily conducted and the heterogeneous sensitizer can be conveniently separated from the products by filtration. They are promising examples for a “green chemistry” since they do not produce waste materials and can be driven by solar light. In a formal way, the overall reaction resembles natural photosynthesis, where light absorption also generates reducing and oxidizing centers, which finally induce the synthesis of organic matter through C–C coupling reactions. The *n*-CdS/*p*-ZnS photocatalyst mimics even the primary processes. Like photosystems I and II the two sulfides absorb the light and enable an efficient charge separation followed by interfacial electron transfer. It is expected that this multifunctional nature of the semiconductor powders can be utilized for further novel preparative reactions, especially in the field of chemical solar energy utilization.

14.1 Introduction

During the past four decades, radical chemistry has undergone a dramatic development. From being considered as mostly sluggish in the early times, although some clean and preparatively useful processes were known, nowadays, radical reactions are mechanistically well understood and therefore occupy an unquestionable position in the toolbox of synthetic methodology. The breakthrough from being a mostly useless to a synthetically highly valuable technology was closely linked to the development of easily controllable radical chain processes, which involve a suitable radical precursor (e.g., halides), a mediator (e.g., transition metal hydrides, such as tri-*n*-butyl tin hydride, *n*Bu₃SnH), and a radical initiator possessing a labile σ bond, which can undergo facile homolytic fragmentation (e.g., peroxides and azo compounds) [1]. Besides comparatively straightforward reactions, such as radical addition to π systems, specifically domino radical processes consisting of two or more consecutive steps involving both intra- and intermolecular reactions are a powerful method to access complex structural frameworks in only few synthetic steps. Since the generally mild conditions for radical reactions are compatible with a large number of functional groups, time-consuming protection strategies can be minimized. In addition to this, the principles of stereocontrol, which were discovered and developed for ionic chemistry, can also be applied to free radical reactions, which have resulted in the development of highly stereoselective radical processes.

Despite the success of radical chain reactions as synthetic tools, the disadvantage associated with the requirement for toxic heavy metal compounds, such as *n*Bu₃SnH, to mediate these transformations has triggered intensive research aimed at the development of less hazardous alternatives. Apart from replacement of *n*Bu₃SnH by tin-free hydrides (e.g., cyanoborohydrides [2] or silanes [3]), organoboranes [4,5], and alternative concepts using the persistent radical effect [6], the development of new photochemical methods to generate charged and noncharged free radical species has become an important area of research in radical chemistry, since it offers the opportunity to perform radical reactions without using environmentally problematic reagents [7].

Irradiation of molecules with UV light leads to their electronic excitation. This rearrangement of electrons within the molecule is associated with a change of chemical properties, compared to those in

SCHEME 14.1 Chemical reactions following photoexcitation of molecules.

the ground state. As illustrated in Scheme 14.1, depending on the molecular structure and the nature of the atoms in the molecule, irradiation can directly lead to the formation of radicals through homolytic scission (photofragmentation) of a suitably labile bond in the electronically excited molecule (Equation 14.1) or initiate inter- or intramolecular hydrogen atom abstraction (Equation 14.2). Compared with a molecule in its electronic ground state, electronic excitation also leads to significantly increased oxidation and reduction properties. This can be used to generate radical anions or cations from reactants in a subsequent step in a process called photo-induced electron transfer (PET) (Equation 14.3).

PET has become a powerful synthetic method, since the usually harsh conditions associated with similar transformations using ground-state chemistry (e.g., toxic heavy metal oxidants, elevated temperatures, and nonneutral pH requirements) can be largely avoided. Photofragmentation is one of the key processes in the chemistry of the atmosphere. For example, the formation and destruction of the stratospheric ozone layer is largely controlled by photo-induced radical reactions in the gas phase.

“Photosensitization” is another mode of action in light-induced chemical reactions, where the energy of the light absorbed by one molecule is transferred to another reactant. Typically, photosensitizers are used (1) in those cases where the reactant molecules themselves only absorb light at wavelengths that are not readily available and/or (2) to access multiplicity states in the reactant that cannot be accessed through direct photo-induced electronic excitation (“forbidden” transitions).

This chapter will focus on a selection of the most recent developments in condensed-phase synthetic radical photochemistry since the publication of comprehensive reviews, for example, Refs. [8–10]. The chemical reactions presented in this chapter are arranged according to the fundamental photochemical process, for example, PET, photofragmentation, and photo-induced energy transfer. Because of the unique position of polymers in material science, radical polymerizations will be treated separately.

14.2 Photochemically Initiated Radical Polymerizations

One of the most efficient processes for the commercial production of high molecular weight polymers proceeds uses radical chemistry. Specifically the reversible addition–fragmentation chain transfer (RAFT) radical polymerization, which was developed by Rizzardo et al. [11], has become a powerful technique for the synthesis of well-defined polymers with low polydispersity and a functionalized end group, as well as polymers with highly complex architecture. In essence, the RAFT process is a living radical polymerization carried out in the presence of xanthates **1** [12], which operate by establishing an equilibrium between propagating polymer radicals $P_{m,n}$ and dormant chains as shown in Scheme 14.2.

SCHEME 14.2 Mechanism of the RAFT process.

SCHEME 14.3 Photo-induced RAFT polymerization for the synthesis of polymethylmethacrylate (PMMA).

Initiation of the RAFT process has mostly been performed using thermal decomposition of a radical initiator. However, it appears that some RAFT agents have a limited thermal stability, which results in a poor control of the polymerization process. Cai et al. [13] have shown that RAFT polymerization of methyl methacrylate (MMA) under UV-vis irradiation using (2,4,6-trimethylbenzoyl)diphenylphosphine oxide (**3**) as photoinitiator leads to narrow distributed polymethylmethacrylate (PMMA) under ambient conditions (Scheme 14.3). Upon irradiation, initiator **3** undergoes Norrish I cleavage to afford 2,4,6-trimethylbenzoyl (**4**) and diphenylphosphonyl (**5**) radicals. The latter have a higher reactivity toward addition to unsaturated substrates compared to aryoyl radicals [14], and are therefore considered as the initiators of the RAFT polymerization process.

Paczkowski et al. developed a number of sulfur-containing initiators for free radical polymerizations. Sodium 4-phenyl-phenylthiosulfonate (**7**, Scheme 14.4) is water soluble and can be used as a photoinitiator of polymerizations of aqueous monomer solutions or of an emulsion polymerization, for example, styrene in water-Triton-X-100 emulsions [15].

Polymeric photoinitiators have received considerable attention in recent years. These are macromolecular systems, which contain chromophores either as pendants or incorporated into the chain, which upon light absorption can produce radical species that initiate polymerization and cross-linking of mono- and multifunctional monomers and oligomers. A couple of photoactive groups have been explored, for example, polymer-linked thioxanthenes **9**, benzil **10**, anthraquinones **11**, and camphorquinone **12** (Scheme 14.5). The initial photochemical step is excitation of the carbonyl group, followed by Norrish I or II type reactions, for example, intramolecular H-transfer. The presence of the polymer chain can in many cases improve the formulation and reduces migration to the film surface, which is of considerable interest for industrial manufacturing of low odor and nontoxic coatings [16].

SCHEME 14.4 Water-soluble initiator for photo-induced radical polymerization processes.

SCHEME 14.5 Polymer-bound photo-initiators for radical polymerization processes.

14.3 Generation of Radicals through Photo-Induced Electron Transfer

Most commonly, PET-induced radical reactions involve an electron transfer sensitizer, which reacts with a substrate in an intermolecular reaction. The resulting substrate radical cation (after oxidative PET) or substrate radical anion (after reductive PET) can be used in subsequent intra- or intermolecular reactions. A recent review on PET sensitization and applications in synthetic organic radical chemistry is given in [17].

14.3.1 Intramolecular Radical Reactions

Using 9,10-dicyanonaphthalene as a mediator for oxidative PET, siloxy cyclopropanes of type **13** can be transformed into β -keto radicals, which can be used in a number of subsequent reactions, for example, through addition to π systems in an intramolecular or intermolecular fashion. In the radical fragmentation/cyclization cascade shown in Scheme 14.6, the initially formed radical cation **14** undergoes opening of the cyclopropyl ring to form a distonic radical cation **15**, which is desilylated by a nucleophile (most commonly the solvent, e.g., acetonitrile). The resulting β -keto radical **16** undergoes a *cis* selective transannular 5-*exo* cyclization to yield the bicyclic ketone **17** after reduction [18].

A radical-cascade access to the skeleton of linear cyclohexano diquinanes, which uses a reductive PET as key step has been reported by Mattay et al. [19] (Scheme 14.7). Electronically excited carbonyl

SCHEME 14.6 Photo-induced oxidative ET as initiator of cascade radical processes.

SCHEME 14.7 Radical cyclization cascade induced by reductive ET.

chromophores are strong electron acceptors, which are capable of inducing oxidation of amines. Thus, photoexcitation of the bicyclic carbonyl compound **18** in the presence of triethylamine leads to formation of the tricyclic compounds **19a** and **b**. The reaction involves reduction of the excited state **18*** by triethylamine to yield the distonic ketyl radical anion **20**, which undergoes an unusual 5-*endo* cyclization. Although this radical cyclization is itself not stereoselective (formation of the *anti* arrangement in **21a** is slightly preferred), the subsequent radical reduction of the tricyclic radical intermediates **21a/b** leads selectively to *cis* fusion between the newly formed cyclopentyl and the cyclohexyl ring.

A similar strategy involving reductive PET has been used to synthesize angularly fused cyclopentanoids and analogues tricyclic systems (not shown) [20]. For a recent review on photoreduction of ketones in the presence of amines and synthetic applications of the resulting ketyl radical anions in intramolecular radical cyclizations see Ref. [21].

14.3.2 Intermolecular Radical Reactions

The strong oxidizing power of the electronically excited carbonyl group in aldehydes, ketones, amides, and imides can be used to induce reductive PET through oxidation of a large variety of different functional groups, for example, amines, activated alkenes, thioethers, and carboxylates. This offers interesting opportunities for the synthesis of complex molecular frameworks through pathways involving intermolecular radical reactions between structurally simpler starting materials.

In the previous section, we focused on the synthetic application of ketyl radical anions obtained through reductive PET of the photoexcited carbonyl compound using tertiary amines as electron donor. This process leads to formation of amine radical cations as by-products, which themselves have also considerable synthetic potential. For example, using a carbonyl chromophore, which cannot undergo Norrish I photochemistry (e.g., benzophenones **22**), reduction in the photoexcited state by a tertiary amine, for example, *N*-methylpyrrolidine (**23**), leads to the radical anion/radical cation pair **24/25**. Subsequent intermolecular proton transfer from **25** to the ketyl radical anion **24** results in formation of a secondary α -amino radical **27** (Scheme 14.8).

The nucleophilic α -amino radicals can be trapped by subsequent addition to electron-deficient alkenes. The example illustrated in Scheme 14.9 shows the catalytic role of the photosensitizer in this sequence. Thus, addition of radical **27** to methylacrylate gives radical adduct **28**, which is reduced to the corresponding stabilized anion **29** by the diphenylhydroxymethyl radical **26**, the by-product during formation of the α -amino radical **27**. Proton transfer from **30** to **29** closes the catalytic cycle for the photosensitizer and gives the final product **31** in excellent yield [22].

The photosensitized addition of anilines to alkenes has been applied to the stereoselective synthesis of polycyclic frameworks, for example, **33**, through a tandem radical addition–cyclization sequence

SCHEME 14.8 Generation of α -amino radicals through oxidative PET.

SCHEME 14.9 Radical addition-cyclization cascade using a catalytic photosensitizer.

SCHEME 14.10 Diastereoselective radical addition-cyclization cascade using oxidative PET as initial step.

involving an aromatic radical substitution step. The stereochemistry of this cascade is controlled by a menthyl substituent attached to the electron-deficient alkene **32** (Scheme 14.10) [23].

Interestingly, addition of thiocarbonyl compounds to the reaction mixture leads to a significant enhancement of the overall rate, regio- and stereoselectivity of the reaction, in addition to activation of otherwise too unreactive amines (not shown). It has been proposed that persistent radical effects could be the origin of this behavior [24].

Mizuno et al. [25] used a reductive PET to perform regio- and stereoselective photoallylation of electron-deficient alkenes with allylic silanes. Scheme 14.11 illustrates quite well the photosensitized reaction of the dicyanomethylene tetrahydronaphthalene **34** with allyl silane **35**, which gives the allylated compound **36a** as the major product, where the allyl group at C-1 and the alkyl residue at C-2 are *trans*. Phenanthrene was used

SCHEME 14.11 Regio- and stereoselective photoallylation of electron-deficient alkenes.

as a sensitizer, which in the electronically excited state transfers an electron to the alkene **34**. Regeneration of the photosensitizer occurs through oxidation of allyl silane **35**, which undergoes desilylation under the release of an allyl radical. The latter is trapped by the alkene radical anion **34**^{•−} at the benzylic carbon to give anion **37**, followed by protonation. The stereochemistry in the major product can be explained by the fact that attack of the allyl radical occurs from the less hindered site, for example, opposite to the substituent at C-2.

It should be noted that in the case of alkyl substituted 1,1-dicyanoethenes radical recombination occurs selectively at the α -site of the alkene moiety, where the unpaired electron is stabilized by the two adjacent cyano groups (not shown) [25].

PET processes can also be used to generate inorganic radicals (this terminology will be used for radicals that do not contain carbon). Electronic excitation of ceric(IV) ammonium nitrate (CAN) through irradiation at $\lambda = 350$ nm results in one-electron reduction of the metal atom with one of the nitrate ligand being the reducing agent (Equation 14.4) [26]. This leads to formation of highly oxidizing nitrate radicals, NO_3^\bullet , which can be trapped by intermolecular reactions. The colorless Ce(III) salt formed as a by-product is (photo)chemically inactive. However, NO_3^\bullet undergoes photochemical decomposition at wavelengths around 650 nm [27].

In contrast to the majority of radicals described so far, NO_3^\bullet has the unpaired electron located at an O atom [28] and is therefore electrophilic. These have been used for the transformation of alkynes into carbonyl compounds through a highly efficient radical addition/cyclization/fragmentation cascade. Scheme 14.12 shows the reaction of photogenerated NO_3^\bullet with the 10-membered cycloalkyne **38** leading to the *cis* fused bicyclic ketones **39** and **40** [29] and the suggested mechanism based on BHandHLYP/6-311G** calculations of the potential surface [30].

The computed activation barriers (E_a) and reaction energies (ΔE) for each step of the sequence are included in Scheme 14.12 (all values include zero-point vibrational energy correction [zpc]) [30].

BHandHLYP/6-311G** energies in kJ mol^{-1} , zpc included

*2.3 without zpc; **3.0 without zpc

SCHEME 14.12 NO_3^\bullet -induced self-terminating radical cyclization cascade of medium-sized cycloalkynes.

The *E*-configured vinyl radical **41** formed through addition of NO_3^\bullet to the π system in **38** (this reaction has a low E_a of only few kJ mol^{-1} and is strongly exothermic [31]) undergoes a 1,5- or 1,6-HAT to the secondary radicals **42a/b**, which subsequently cyclize in a *cis* selective 5-*exo* or 6-*exo* fashion, respectively, to the C=C double bond to yield the α -nitrato radicals **43a/b**. The key step in the cyclization cascade is the practically barrierless and highly exothermic β -fragmentation of the O- NO_2 bond in the latter radical intermediates to give the ketones **39** and **40** under the release of nitrogen dioxide, NO_2^\bullet . According to the computations, each individual step in this cascade is not only strongly exothermic, but also associated with a low E_a .

The discovery of this sequence closes a long-existing gap in synthetic radical chemistry. Intermolecular addition of O-centered radicals to π systems, specifically to C \equiv C triple bonds, which offers the unique opportunity to form C-O bonds under mild conditions, have in the past not received much attention. This could originate from the perception that O-centered radicals, such as alkoxyl radicals, RO^\bullet , or acyloxyl radicals, RC(O)O^\bullet , may not react with π systems through intermolecular addition at rates that are competitive to other pathways, for example, allylic hydrogen abstraction or β -fragmentation, respectively. With the inorganic NO_3^\bullet , such complications could apparently be avoided. Thus, with NO_3^\bullet alkynes can be easily oxidatively functionalized. The mechanism in Scheme 14.12 shows that NO_3^\bullet can formally be regarded as a synthon for O-atoms in solution. Because the released NO_2^\bullet is too unreactive to initiate a radical chain process under the applied reaction conditions, this sequence is termed a “self-terminating oxidative radical cyclization”: the cascade-initiating radical contains the unreactive leaving group, which is released in the final step to terminate the sequence. In contrast to reactions performed under “classical” radical chain conditions and which are nearly always associated with a loss in overall functionality of the molecule, in self-terminating radical cyclizations the net amount of functional groups is unchanged after the reaction.

The initially formed vinyl radical can also be trapped through cyclization onto a carbonyl bond. For example, reaction of electro- or photochemically generated NO_3^\bullet with 5-cyclodecynone (**44**) leads to the isomeric epoxyketones **45** and **46** (Scheme 14.13) [29].

Since cycloalkyne **44** is not symmetrical, NO_3^\bullet addition to the C \equiv C triple bond gives the isomeric nucleophilic vinyl radicals **47** and **50**, which undergo 5-*exo* or 6-*exo* cyclization, respectively, to the less electron-rich carbon end of the carbonyl C=O double bond. The resulting allyloxyl radicals **48** and **51** cyclize in a 3-*exo* fashion to yield the α -oxiranyl radicals **49** and **52**, respectively. In accordance

SCHEME 14.13 NO_3^\bullet -induced self-terminating radical cyclization cascade of medium-sized cyclolalkynones.

SCHEME 14.14 Diastereoselective formation of anellated tetrahydrofurans and pyrrolidines through an NO_3^\bullet -induced self-terminating radical cyclization cascade.

with literature [32], the calculations show that this latter step is highly reversible, and the only reason why the reverse ring-opening does not occur in this cascade is the ease by which the radicals **49/52** undergo β -fragmentation to give the respective epoxy ketones **45** and **46** with release of NO_2^\bullet . This self-terminating radical cyclization represents one of the very few examples for the synthetic access to epoxides through a 3-*exo* cyclization of allyloxyl radicals. Interestingly, this sequence can also formally be considered as “retro-Eschenmoser-Ohloff” fragmentation [33].

Self-terminating radical oxygenations are not restricted to cyclic alkynes. Electro- and photochemically generated NO_3^\bullet can be used for the oxidative cyclization of cycloalkyl-clamped alkynes **53** (Scheme 14.14). This reaction leads to the formation of anellated tetrahydrofurans (**54** with $X = O$) [34–36] or pyrrolidines (**54** with $X = NTs, NTF$) [37] possessing four asymmetric centers in good to excellent yields through a cascade consisting of radical addition at the less hindered site of the $C\equiv C$ triple bond, rate-determining 1,5-HAT [34,36], 5-*exo* cyclization, and terminating β -fragmentation under release of NO_2^\bullet . The diastereoselectivity of this sequence, which is determined in the 5-*exo* cyclization, ranges from moderate to very high and depends on various factors, such as the nature of the heteroatom X and the substituent R .

The role of the cycloalkyl clamp in the starting alkyne **53** is to reduce the conformational degrees of freedom in the intermediate highly reactive vinyl radical **55**, and to achieve a favorable alignment between the SOMO on the π system and the σ -orbital of the respective C–H bond for the 1,5-HAT. The experiments revealed that the self-terminating cyclization cascade worked best using a *cis*-1,2-disubstituted cyclopentyl clamp, however, *trans*-1,2-disubstituted cyclohexyl rings could also be used. With larger ring sizes, both yield and diastereoselectivities were reduced [34–36]. A similar conformational restriction of the intermediate vinyl radical was also obtained using the Thorpe–Ingold effect provided by two geminal ester groups (not shown) [38].

Apart from “typical” radical chemistry, photogenerated NO_3^\bullet can also be used in ET reactions. Due to the high oxidation power of NO_3^\bullet ($E^0(NO_3^\bullet/NO_3^-) = 2.3\text{ V vs. NHE}$ [26,39,40]), many organic compounds are principally prone to oxidation by NO_3^\bullet [26]. With regard to the intrinsic perception that radicals are “damaging” species and contact with environmental radicals should therefore be avoided, it was interesting to realize that NO_3^\bullet , which are the most important oxidants in the nighttime troposphere, can mediate repair of pyrimidine cyclobutane dimers in DNA. The latter are the primary photoproducts formed through UV-light-induced [2 + 2] cycloaddition between two adjacent pyrimidine bases in the same oligonucleotide strand. This damage, if not repaired, can lead to mutations, cell death, and cancer [41]. Scheme 14.15 shows the results of an *in vitro* study using the *cis,syn* permethylated uracil dimer **58** as simplified model for pyrimidine cyclobutane dimers in DNA, which undergo rapid and efficient cleavage into the respective monomer **59** upon treatment with photogenerated NO_3^\bullet [42].

SCHEME 14.15 NO_3^\bullet -induced oxidative repair of pyrimidine cyclobutane dimers.SCHEME 14.16 NO_3^\bullet -induced oxidative damage of aromatic amino acids.

Reaction of photogenerated NO_3^\bullet with electron-rich aromatic compounds of type **60** is a convenient method to oxidatively modify the benzylic position (Scheme 14.16) [26,43]. The reaction is likely to proceed through ET to give radical cation **61**, which loses a proton at the benzylic position to restore the aromatic system. Direct H abstraction from the benzylic position by NO_3^\bullet could be excluded, since the intermediate aromatic radical cation **61** could be trapped by additives, such as nitrogen dioxide, NO_2^\bullet . Thus, treatment of the enantiomerically pure phenylalanine derivative **S-63** with NO_3^\bullet leads to formation of the diastereomeric β -nitrate esters *threo/erythro*-**64** with a ratio of 11:1 [43]. The reason for the high diastereoselectivity of this reaction, which offers interesting synthetic opportunities, is not yet clear.

It should be noted that reaction of tyrosine with photogenerated NO_3^\bullet leads to the formation of 3-nitrotyrosine (not shown), which is a known biomarker for nitrosative stress and has been linked to respiratory tract diseases, such as asthma [43]. With regards to the role of NO_3^\bullet in atmospheric chemistry, this reaction may provide a novel and so far unknown, pollution-derived pathway to 3-nitrotyrosine.

14.4 Radical Reactions Induced by Photofragmentation

Generation of radicals through unimolecular fragmentation of a labile bond in a photoexcited molecule offers unique advantages over conventional radical chain conditions, where formation of the target radical species usually involves at least one bimolecular step. In the past years, new photocleavable groups have been designed, which are structurally based on the thiohydroxamate esters **65** developed by the Barton group in 1983 (Scheme 14.17) [44,45]. They all possess a labile N–O bond, which upon cleavage gives initially an O-centered radical **67**. Depending on the nature of the substituent R, the latter can either react directly as O radical or undergo fragmentation to produce a secondary radical, which then reacts in a subsequent step. Whereas the Barton esters **65** are generally readily accessible from commercially available precursors, their extreme light sensitivity makes handling a tricky task. This difficulty could be overcome with the open-chain thiohydroxamates **68**

SCHEME 14.17 Photolabile radical precursors.

developed by Kim et al. [46] or Hartung's thiazolthiones **70** [47], respectively, which have a higher stability toward visible light and require UV light to induce fragmentation.

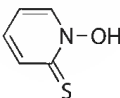

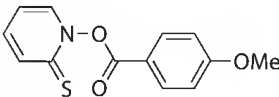

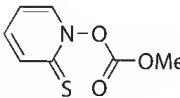

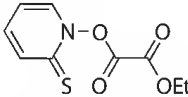

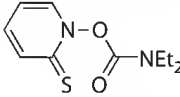

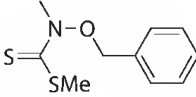

Barton and Kim esters were used to generate a large variety of both inorganic and organic *O*-centered radicals and explored in self-terminating radical cyclizations. Using the reaction with cyclodecyne (**38**) as model system (see Scheme 14.12), hydroxyl (HO^\bullet) [48], acyloxyl ($\text{RC}(\text{O})\text{O}^\bullet$) [49], alkoxycarbonyloxyl ($\text{ROC}(\text{O})\text{O}^\bullet$) [50], alkoxycarbonylacyloxyl ($\text{ROC}(\text{O})\text{C}(\text{O})\text{O}^\bullet$) [50], carbamoyloxyl ($\text{R}_2\text{NC}(\text{O})\text{O}^\bullet$) [50], and alkoxy radicals (RO^\bullet) [51] have been shown to promote the oxidative cyclization to the bicyclic ketones **39** and **40**. Although the organic *O*-centered radicals are known to undergo facile β -fragmentation, under optimized conditions, they could be very efficiently trapped by the alkyne prior to decomposition. In Table 14.1 are shown representative outcomes of these reactions.

It should be noted that with some of these *O*-centered radicals, the terminating β -fragmentation of the *O*–*R* bond in the α -oxo radicals of type **43** (see Scheme 14.12, with the NO_2 group being replaced by the respective organic residue) could be energetically challenging. Computational studies suggest that alternative termination pathways may also be active that could involve a radical chain process with the precursor of the respective *O*-centered radical (not shown) [30].

The apparent generality of self-terminating radical cyclizations with regards to different classes of *O*-centered radicals led to the question, whether this sequence could also be applied to other heteroatom-centered radicals, for example, those where the unpaired electron is located on a nitrogen atom. Quite remarkably, only very few examples for radical cascades that are initiated by intermolecular addition of *N*-centered radicals to alkynes have been reported.

Scheme 14.18 shows that reaction of phthalimidyl radicals, Im^\bullet , which were generated through photochemical cleavage of the *N*–*Br* bond in *N*-bromo phthalimide, with cyclodecyne (**38**) leads to formation of small amounts of unsaturated bicyclic compounds **72** and **73** amongst other products (not shown) [52]. The 10-membered cycloalkyne **38** is a versatile model system for self-terminating radical reactions, since the reaction steps following initial radical addition to the $\text{C}\equiv\text{C}$ triple bond are driven by transannular interactions and are therefore highly regioselective. Thus, initial addition of Im^\bullet initiates the expected radical translocation sequence consisting of transannular HAT (**74** \rightarrow **75a/b**), followed by transannular radical cyclization (**75a/b** \rightarrow **76a/b**). In contrast to the self-terminating radical

TABLE 14.1 Representative Results for the Reaction of Cyclodecyne (38) with Various O-Centered Radicals

cyclizations with O-centered radicals presented earlier, however, β -fragmentation in the α -imidyl radical intermediates **76a/b** is not possible, since no stable radical could be released. It is therefore believed that the reaction proceeds through trapping of **76a/b** by bromine atoms, which are formed as by-products during photolysis of *N*-bromophthalimide. The resulting tertiary bromides **77a/b** could subsequently eliminate hydrogen bromide to give the final products **72** and **73**, respectively.

**SCHEME 14.18** Self-terminating radical cyclization cascade involving N-centered imidyl radicals.

Self-terminating radical cyclizations have been explored with both aminium and amidyl radicals using the well-established model reaction with cyclodecyne (**38**). The aminium radicals were produced through photolysis of the respective *N*-nitroso or *N*-chloroamines under acidic conditions, whereas the amidyl radicals were obtained from photochemical cleavage of *N*-nitrosoamides. Surprisingly, instead of the expected bicyclic *N*-containing products, ketones **39** and **40** were exclusively formed in these reactions. This finding could be explained by the exemplary mechanism shown for the reaction of the *N*-benzyl acetamidyl radical, AcBnN[•], in Scheme 14.19 [53].

N-Radical addition to the C≡C triple bond in cycloalkyne **39** initiates the usual transannular radical translocation/cyclization cascade, which is terminated by β-fragmentation **80** → **81**. The observed bicyclic ketones **39/40** could result from subsequent hydrolysis of the imides **81a/b**. However, experimental findings indicate that the mechanism is more complex. Although the *N*-radicals were equipped with substituents that should form in principle stable radical leaving groups in the terminating β-fragmentation **80** → **81**, namely benzyl or tosyl, no apparent correlation between radical stability and yield of bicyclic

BHandHLYP/6-311G** energies in kJ mol⁻¹, zpc included

SCHEME 14.19 Self-terminating radical cyclizations involving *N*-centered aminium and amidyl radicals.

ketones **39/40** was found. It even appeared that N-radicals with primary alkyl substituents, which should not be released as radicals at all, performed significantly better in this cyclization sequence than N-radicals carrying substituents possessing good or excellent radical stabilizing properties (see table in Scheme 14.19).

Mechanistic insights were obtained from extensive computational studies of the potential energy surface of this reaction and the termination step. Selected BHandHLYP/6-311G** data given in Scheme 14.19 for the reaction of AcBnN• show the overall exothermicity of the initial radical addition and the subsequent transannular radical translocation steps. Calculations of the redox properties of α -nitrogen radicals of type **80** and of the various N-centered radicals revealed that the latter are sufficiently strong oxidants to promote oxidation of the α -nitrogen radical to the respective iminium ions **82** (data not shown). Subsequent hydrolysis leads to the ketones **39/40**. Thus, in this sequence, the N-radicals have a dual role, first as initiator of the radical cyclization cascade, and second as terminator of the sequence through a redox process. This is a highly interesting variation of self-terminating radical cyclizations.

Photochemical cleavage of the S–S bond in disulfides has been used to generate thiyl radicals, which can be trapped through addition to alkynes. In the model reaction with cyclodecyne (**38**) the initial radical addition triggers a transannular radical translocation/cyclization, similar to the reaction shown in Scheme 14.12. The products in this sequence are three stereoisomeric bicyclic thiols **83** possessing a decalin [4.4.0] framework, which result from reduction of the intermediate α -thio radical **84** (Scheme 14.20). Products possessing the constitutionally isomeric bicyclo[5.3.0] framework (as observed in the reaction of **38** with O- and N-centered radicals shown earlier, respectively) were not formed [54].

In contrast to self-terminating radical cyclizations with O- and N-centered radicals, respectively, where exclusively *cis*-fused bicyclic systems were obtained (as would be expected for kinetically controlled radical cyclizations), the reaction with S-centered radicals leads also to *trans*-fused products. Mechanistic studies using computational techniques revealed that the difference between the reactions of O- or N-centered radicals, respectively, compared to those involving S-centered radicals is caused by the reversibility (and endothermicity) of the initial S-radical addition to the alkyne C \equiv C triple bond, which leads to another low-energy conformational isomer of the vinyl radical. The subsequent transannular reaction of the latter occur in a regio- and stereospecific fashion, where formation of the bicyclo[4.4.0] framework is kinetically much more favorable than formation of the isomeric bicyclo[5.3.0] framework [55].

Needless to say, apart from generation of heteroatom-centered radicals, photofragmentation is also a versatile method to generate C-centered radicals in a direct fashion. The xanthate group exploited by Zard et al. [12], which has found important application in the RAFT living polymerization process (see previous paragraphs), has inspired the development of dithiocarbamates as highly efficient precursor for carbamoyl radicals [56]. The example in Scheme 14.21 shows cyclization of a carbamoyl radical **87**, which was obtained through light-driven dissociation of dithiocarbamate **85**, in a *cis*-selective 4-*exo* fashion. The resulting bicyclic radical intermediate **88** initiates a diastereoselective group transfer reaction (the radical **88** is attacking with the less hindered site) with xanthate **85** to give the final bicyclic β -lactam **86**.

SCHEME 14.20 Self-terminating radical cyclization cascade involving S-centered thiyl radicals.

SCHEME 14.21 Diastereoselective cyclization of carbamoyl radicals generated through photolysis of dithiocarbamates.

14.5 Photosensitized Radical Reactions

Energy transfer from a photoexcited donor molecule to an acceptor in the electronic ground state offers highly interesting opportunities for synthetic applications. The most common process is triplet sensitization using carbonyl compound as donor. Excitation, followed by intersystem crossing, leads to the triplet excited state ($^3n\pi^*$ in carbonyl compounds). The triplet character can subsequently be transferred to an acceptor, for example, an alkene, which is photochemically inactive under these conditions. Abe and Hoffmann et al. have used this chemistry to perform stereo- and regioselective radical reactions involving furanone derivatives using acetone as triplet sensitizer (Scheme 14.22) [57].

via (simplified system):

SCHEME 14.22 Triplet-sensitized stereo- and regioselective formation of furanones.

The key step in these reactions is the 1,5-HAT in a triplet biradical of type **91*** obtained by energy transfer, leading to the stabilized the biradical **92**, which undergo an intramolecular radical recombination. When this sequence is applied to the α -glycosyl substituted furanone **89**, radical recombination occurs in a highly stereoselective fashion and leads exclusively to the complex tricyclic compound **90** with a remarkable yield.

15.1 Introduction

Nucleophilic substitution is feasible through processes that involve electron transfer (ET) steps. In these reactions, a compound bearing an adequate leaving group is substituted at the *ipso* position by a nucleophile. Several reviews have been published on the subject in relation to the mechanism and to the synthetic applications of the process, which has become one of the common methodologies in modern synthesis.¹ In this review, we will describe the most recent advances in photostimulated $S_{RN}1$ reactions. With this aim in mind, we expect to cover recent $S_{RN}1$ substitutions, with an emphasis on the scope of the process in terms of synthetic capability and target applications. The critical review illustrates the mechanistic considerations required for planning synthetic applications and a wide range of synthetic protocols.

The $S_{RN}1$ reaction, which stands for unimolecular radical nucleophilic substitution, is a chain process that involves radicals and radical anions as intermediates. Several nucleophiles can be used for $S_{RN}1$ reactions such as carbanions and heteroatom anions resulting in the formation of new C–C or C–heteroatom bonds in good yields. An exception to this is the reaction of aromatic alkoxides with aromatic substrates. In these cases, C–O bond formation is not observed; instead C–C bond formation is achieved. For example, the unsubstituted phenoxide ions have been reported to react with ArX to afford the *ortho*- (ca. 40%) and *para*- (ca. 20%) C–C coupled products.¹ On the other hand, alkoxide ions afford the *O*-alkylation products with aliphatic substrates with electron withdrawing group (EWG) at the α -carbon.

There is a theoretical study (DFT/B3LYP level) on the reaction of aromatic alkoxide ions with phenyl and 4-nitrobenzyl radicals with the aim of interpreting the factors that control the regiochemical outcome of these reactions. While FMO predicts the experimental regioselectivity of phenyl radicals with good accuracy, it fails in the nitrobenzyl case.²

A similar behavior is observed with nitrogen nucleophiles (anions from aromatic amines, pyrrole, diazoles, and triazoles) in reactions with aromatic substrates, no C–N is observed, but C–C bond is formed. On the other hand, with nitrogen nucleophiles N-alkylation products are formed with aliphatic substrates with EWG at the α -carbon.

Anions derived from tin, phosphorus, arsenic, antimony, sulfur, selenium, and tellurium react through the heteroatom to form a new C–heteroatom bond by this mechanism.

15.2 Mechanism

The $S_{RN}1$ mechanism is presented in Scheme 15.1. In the initiation step, the radical anion of the substrate can be formed by an ET from the nucleophile or from a suitable electron source. This radical anion fragments into a radical and the anion of the leaving group. On the other hand, the ET to unsubstituted alkyl halides is proposed to be a dissociative reaction.³

The radical can react with the nucleophile to give the radical anion of the substitution product, which by ET to the substrate forms the intermediates needed to continue the propagation cycle. The mechanism has termination steps that depend on the substrate, nucleophile, and experimental conditions.

Inhibition by radical traps has been extensively used to provide mechanistic evidences. The most commonly employed are di-*t*-butylnitroxide or radical anion scavengers such as *p*-dinitrobenzene (*p*-DNB).

Radical probes have also been used in order to assess the formation of radicals along the propagation cycle. Products from ring closure, ring opening, or rearrangement of the radicals were thus taken as evidence of the presence of these intermediates.

The process offers the possibility to afford the substitution of an unreactive nucleophile through *entrainment*⁴ conditions. Entrainment is useful when the nucleophile is rather unreactive at initiation, but quite reactive at propagation. Under these conditions the addition of another nucleophile, more reactive at initiation, increases the generation of intermediates and allows the less reactive nucleophile to start its own propagation.

Spontaneous or thermal ET is a possible initiation depending on the relationship between the electron affinity of the substrate and the oxidation potential of the nucleophile; however, few examples are known. Even though photoinduction is a widely used initiation method, there are not many mechanistic studies. These photoinduced ET can conceivably be accomplished in one of the following mechanisms: (1) homolytic cleavage of the C–X bond, (2) ET from the nucleophile to the excited RX (or from the excited nucleophile to the RX), (3) ET from excited charge transfer complex (CTC) of the nucleophile and RX. Depending on the nature of the RX, the nucleophile, and the experimental conditions, any of these mechanisms could probably be considered as an initiation step.

One of the main goals of the $S_{RN}1$ mechanism is the possibility to obtain disubstituted compounds when the reaction is performed with substrates bearing two leaving groups. Few examples are known of trisubstitutions⁵ or four consecutive $S_{RN}1$ substitutions.^{6,7}

SCHEME 15.1 Representation of the mechanism of the $S_{RN}1$ reaction.

15.3 Aromatic Substrates

15.3.1 Reaction with Carbanions

Aromatic substrates bearing suitable leaving groups can suffer substitution by the $S_{RN}1$ mechanism with a large range of nucleophiles under different reaction conditions. The most widely used nucleophiles are carbanions, such as those derived from ketones, esters, *N,N*-disubstituted amides, etc. The solvents and conditions of choice are usually liquid ammonia or DMSO and irradiation.

When dihalobenzenes react with aliphatic ketone enolate anions, disubstitution products are formed. Under irradiation, as well as under $FeBr_2$ initiation, *o*-iodohalobenzenes **1** ($X = Cl, Br, I$) react with enolate anions of aromatic ketones, such as acetophenone, propiophenone, and 2-naphthyl methyl ketone in DMSO. For example, the photostimulated reaction of 2-naphthyl methyl ketone ions (2-NaphCOCH₂[−]) with **1** forms the radical **2** after C-I bond fragmentation that reacts with the nucleophile to afford the radical anion **3**^{•−}, in which the odd electron is localized in the ArCO- π moiety (Scheme 15.2). The rate of intermolecular ET to **1** to yield **3** is faster than the intramolecular ET to σ^* MO of the C-X bond, giving monosubstitution product **3** with retention of one halogen (Cl: 71%, Br: 86%, I: 65%).⁸

The extent of dehalogenation is discussed in terms of the energetics of the intramolecular ET from the MO ArCO- π^* to the σ^* MO of the C-X bond in the monosubstituted radical anions **3**^{•−} proposed as intermediates.⁸

The photostimulated reaction of a chiral-assisted imide enolate ion **4** with 1-iodonaphthalene provides an example of stereoselective coupling of an aromatic radical with a nucleophile. In this reaction the diastereomeric isomers of the substitution compound are formed (43%–64%) and the selectivity observed is highly dependent on the metal counterion used and its chelation properties (Equation 15.1). All the ions studied (Li⁺, Na⁺, K⁺, Cs⁺, Ti⁴⁺) are selective; however, the highest stereoselectivity is found with Li⁺ at low temperature (−78°C) and with Ti⁴⁺ (d.r. >98%, S/R).⁹

The photostimulated reaction of 4-iodo-1,1,2,2,9,9,10,10-octafluoro[2.2] paracyclophane (**5**) with stabilized carbanions gives good yield of substitution product. For example, the reaction with dimethyl malonate anion affords 85% of the substitution product **6** (Equation 15.2).¹⁰

SCHEME 15.2 Mechanism proposed to obtain monosubstitution product from dihalobenzenes **1** and 2-naphthylmethyl ketone enolate anions.

Aryl radicals couple with 2-naphthoxide ions in the position one to form a C–C bond, and the rate of coupling were determined.¹¹ When the aryl radical has *ortho*-substituents, the amount of reduced product increases. The anion of 9-phenanthrol shows a similar behavior in the photostimulated reaction with PhI, the product 10-phenylphenanthren-9-ol is obtained in 53% yield.¹²

2-Naphthylamide ions react by a photoinduced $\text{S}_{\text{RN}}1$ process with ArI in liquid ammonia, and 1-aryl-2-naphthylamines are formed in 45%–63%.¹³ This approach has been used for the synthesis of 10-aryl-9-aminophenanthrene by reaction of the anion of 9-aminophenanthrene with different ArX [(ArX = PhI (100%), 4-MeOC₆H₄I (81%), 4-MeC₆H₄I (75%), 9-bromophenanthrene (93%)].¹²

15.3.2 Reaction with Tin Nucleophiles

Chloroarenes undergo substitution by Me_3Sn^- ions in liquid ammonia under irradiation to afford ArSnMe_3 in high yields (88%–100%). On the other hand, ArBr and ArI react by an HME reaction.¹⁴ The reactions of *o*-, *m*-, and *p*-C₆H₄Cl₂ with Me_3Sn^- ions furnish products arising from disubstitution in 58%, 90%, and 88% yields, respectively.⁵ For the synthesis of Me_3SnAr not only ArCl but also phenols are used as starting substrates through the intermediacy of $(\text{EtO})_2\text{P}(\text{O})\text{OAr}$ esters. These syntheses proceed in high yields.¹⁵ From 1- and 2-naphthyl diethylphosphate, for instance, 1-naphthyl (93%) and 2-naphthyl (98%) trimethylstannanes were obtained.

The photoinduced reaction of the $\text{Me}_2\text{Sn}^{2-}$ dianion with ArCl (ArCl = 4-MeOC₆H₄Cl, 4-MeC₆H₄Cl, 4-NCC₆H₄Cl, and 1-ClC₁₀H₇) gives functionalized Ar_2SnMe_2 in good yields (68%–85%) in liquid ammonia. These stannanes are used in homocoupling reactions in the presence of $\text{Cu}(\text{NO}_3)_2 \cdot 2.5\text{H}_2\text{O}$ to prepare almost quantitatively the corresponding biaryls.¹⁶

15.3.2.1 Cross-Coupling Reaction

The coupling of the tin products obtained from $\text{S}_{\text{RN}}1$ reactions with an ArI through a Pd-catalyzed process has been developed to obtain polyarylated compounds in a two step-one pot reactions. Thus, from *m*- and *p*-dichlorobenzenes, *m*- and *p*-terphenyls were obtained in 76% and 71% yield, respectively.¹⁷ Following the same process, 1,3,5-triphenylbenzene was obtained in high yields from 1,3,5-C₆H₃Cl₃. This has been the first report of a trisubstitution by a cross-coupling reaction catalyzed by Pd.⁵

The fact that ArCl reacts with Me_3Sn^- ions under irradiation to form ArSnMe_3 and that the reactivity of ArI in the Pd-catalyzed reaction with stannanes is much greater than that of ArCl, a substrate bearing both leaving groups will react faster by the C–I bond via a chemoselective cross-coupling reaction with a stannane catalyzed by Pd. This will allow the remaining leaving group, chlorine, to react later in another $\text{S}_{\text{RN}}1$ -type reaction to form an organotin intermediate, which can subsequently furnish product by a cross-coupling Pd-catalyzed reaction. This tandem strategy has been used as shown in Equation 15.3. Using this sequential scheme of combined transformations, high yields of other polyaromatic compounds are obtained.¹⁸

A similar approach based on the different reactivities of ArBr and ArOP(O)(OEt)₂ in Pd-catalyzed cross-coupling reactions is applied to the synthesis of asymmetric triaryl compounds in acceptable yields. Mixed biaryl compounds are also obtained in moderate yields through an S_{RN}1–Stille sequence.¹⁹

The synthesis of 6-substituted uracils in a three-step reaction (S_{RN}1–Stille–hydrolysis) is accomplished in good yields using commercial 6-chloro-2,4-dimethoxypyrimidine as the starting substrate (Scheme 15.3).²⁰

When this novel three-step approach was applied to a one-pot reaction, 6-aryl uracils (1-naphthyl, 4-chlorophenyl, 3-chlorophenyl, 2,3,4,5,6-pentafluorophenyl) were formed and isolated (43%–57%) as pure products. When acid chlorides were the electrophiles (6-benzoyl and 6-(3-chlorobenzoyl)), uracils were obtained in 49%–54% of isolated yields.²⁰

Methyl 2,5-dichlorobenzoate **7** was studied as a model compound of certain chlorinated herbicides. It was found that **7** reacted with Me₃Sn[−] ions in liquid ammonia under irradiation to afford disubstitution product **8** in 99% yield and only trace of product **9** (Equation 15.4). However, in the dark, **7** reacted with Me₃Sn[−] ions to give the mono-substitution product **9** in 81% yield.^{21,22} The dark reaction is inhibited by di-*tert*-butyl nitroxide, which indicates that **9** is formed by the S_{RN}1 mechanism with a spontaneous ET from the nucleophile to **7** to initiate the reaction.

Other chlorinated herbicides were also studied. The stannanes thus synthesized reacted with electrophiles by a Pd-catalyzed reaction, and the products were tested to know their phytotoxicity.²²

Arylboronic acids are easily available via transmetalation between ArSnMe₃ and borane in THF. Consequently, a variety of arylpolyboronic acids is achieved from the stannanes previously synthesized by the S_{RN}1 mechanism from ArCl²³ or ArOP(O)(OEt)₂²⁴ in around 80% yields. These arene di- and tri-boronic acids can be used as starting materials for the synthesis of polycyclic aromatic systems via double or triple Suzuki cross-coupling reactions.^{23,24}

SCHEME 15.3 Tandem reactions to synthesize 6-substituted uracils.

15.3.2.2 Electrophilic Reactions

The exceptional leaving group ability of the trimethylstannyl group in electrophilic aromatic substitutions allows the synthesis of asymmetric diaryl ketones in good yields (40%–78%) through the reaction of trimethylarylstannanes, synthesized by photostimulated $S_{RN}1$ reactions, with acyl chlorides in catalyst-free syntheses in chlorobenzene at 130°C. In addition, these reactions are completely regioselective making possible the synthesis of diarylketones, which are not usually available under Friedel–Crafts reactions. The reaction of stannane **10** with benzoyl chloride, for instance, furnished diarylketone **11** in 78% yield (Equation 15.5).²⁵

These reactions have been used, in a single step, in the synthesis of bi- and triaroylarenes through the reaction of bi- and tristannylarenes with different aroyl halides. Specific di- and triketones are obtained in good to excellent yields (45%–83%).²⁶

15.3.3 Reaction with Sulfur Nucleophiles

In general, PhS^- ions react with ArI in liquid ammonia under photostimulation to afford good yields of ArSPh or heteroaryl-SPh (70%–100%).^{1a} The reactivity of other sulfur nucleophiles such as thio-urea anion²⁷ and thioacetate anion²⁸ in photostimulated $S_{RN}1$ reaction has been reported as a one-pot, two-step method for the synthesis of several sulfur-aromatic compounds from moderate to good yields.

These photostimulated reactions with ArX are examples of fragmentation of the radical anion intermediate into a new radical and anion capable of continuing the propagation cycle of the $S_{RN}1$.²⁹ After the coupling of the aryl radical with urea anion **12** as an example, the radical anion intermediate **13** thus formed fragments into ArS^- and a new carbon-centered radical **14** (Equation 15.6). The deprotonation of the latter afforded a new radical anion intermediate **15** that transfers the odd electron to the ArX to continue the propagation steps (Equation 15.7).

The ArS^- ions obtained are quenched with MeI to yield ArSMe in a one-pot procedure, together with Ar_2S in variable yields, from an $S_{RN}1$ between ArS^- ions and aryl radicals. When substrates have EWG, the yields of ArSMe are good (49%–87%).²⁷

With the ArS^- ions thus formed a variety of sulfur compounds have been synthesized. By protonation of the reaction products were obtained ArSH (80%), by oxidation ArSSAr (70%), and by reaction with PhI in another $S_{RN}1$ reaction, ArSPh were obtained in 35% yield.²⁸

The photostimulated reaction of **12** with **16** ($\text{R}=\text{Me}$), and after quenching the reaction with MeI , yielded the substitution product **17** ($\text{R}=\text{Me}$) in 97% yield (Equation 15.8).³⁰

However, with **16** ($R = \text{CH}_2\text{Ph}$) as substrate only the reduction product was observed and it was attributed to a 1,5-hydrogen shift from the benzylic H to the aryl radical intermediate. On the other hand, with the substrate **18**, the product **19** and the rearranged products **20** and **21** were obtained in 10%, 38%, and 25% yield, respectively (Equation 15.9).

The straightforward product **19** is the reaction of the radical **22** with **12** in the sense of Equation 15.8. A competitive reaction is that the radical **22** intermediate, by an 1,6-hydrogen shift, gave the rearranged radical **23** followed by a 1,4-aryl migration through the spiro radical **24**. Coupling reaction of anion **12** to the *para* position of **24**, followed by fragmentation, proton transfer, and ring opening of the spiro intermediate, afforded a thiolate anion. Quenching with MeI finally yielded the product **21** (Equation 15.10).

The spiro radical **24** also afforded an amidyl radical by ring opening. This nitrogen-centered radical can be reduced by hydrogen atom abstraction from the medium to give the rearranged amide **20**, the main product of this reaction.³⁰

4-Iodo-1,1,2,2,9,9,10,10-octafluoro[2.2]paracyclophane (**5**) undergoes high-yield nucleophilic substitution with PhS^- , $2\text{-MeC}_6\text{H}_4\text{S}^-$, $3\text{-MeC}_6\text{H}_4\text{S}^-$ ions by the photoinduced $\text{S}_{\text{RN}}1$ mechanism, providing ready access to a new group of paracyclophane derivatives in 88%, 70%, and 91% yields, respectively.¹⁰

15.3.4 Ring Closure Reactions

15.3.4.1 $\text{S}_{\text{RN}}1$ Reaction Followed by a Polar Reaction

An approach to bring about a ring closure reaction could be developed by using a substrate with an appropriate substituent *Z* *ortho* to the leaving group, such as **25**, which can react with a nucleophile by the $\text{S}_{\text{RN}}1$ mechanism to afford product **26**. The ring closure product **27** is achieved by the spontaneous reaction between the Nu group and *Z* (Equation 15.11).

SCHEME 15.4 Synthesis of 2-substituted indoles and 2-phenyl-3H-benzo[e]indole.

Indoles. An important example is the synthesis of indoles by the photostimulated reaction in liquid ammonia of *o*-iodoaniline with carbanions derived from aliphatic and cyclic ketones to give the substitution product that spontaneously afford substituted indoles.

The photostimulated reactions of *o*-iodoaniline with enolate anions of aromatic ketones yield 2-substituted indoles **28a–f** (Scheme 15.4).³¹ Furthermore, the photostimulated reaction of 1-bromo-2-naphthylamine with PhCOCH_2^- anion in DMSO affords 2-phenyl-3H-benzo[e]indole **28g** (Scheme 15.4).^{31b}

The photostimulated reactions of *o*-iodoaniline with enolate anions of cyclic ketones afford the fused indoles in moderate to high yields (Scheme 15.5).^{31b} Fused indoles with OMe groups as substituent have been synthesized by the same methodology.³²

Isoquinolin-1(2H)-ones. The synthesis of 3-substituted isoquinolinones can be performed by the photoinduced $S_{\text{RN}}1$ reactions in DMSO of *o*-iodobenzamide with enolate ions of aromatic (acetophenone, 1- and 2-naphthyl methyl ketones, 2-, 3- and 4-acetyl pyridine) and aliphatic ketones (1-adamantyl methyl ketone) in 68%–87% yields.³³ With cyclic ketones the reactions afforded fused isoquinolinones with good yields (Scheme 15.6).

2H-1,2-Benzothiazine 1,1-dioxides. 2-Iodobenzenesulfonamide undergoes photostimulated $S_{\text{RN}}1$ reactions in liquid ammonia with enolate ions derived from acetone, pinacolone, 3-methyl-2-butanone, cyclopentanone, cyclohexanone, and cyclooctanone to give fair to good yields of 2H-1,2-benzothiazine-1,1-dioxides (Scheme 15.7).³⁴ On the other hand, ethyl ketone enolate ions such as 3-pentanone and 2-methyl-3-pentanone gave low yields of corresponding benzothiazine and reduction of substrate was the predominated product.

SCHEME 15.5 Synthesis of fused indoles.

SCHEME 15.6 Synthesis of fused isoquinolinones.

SCHEME 15.7 Synthesis of 2H-1,2-benzothiazine 1,1-dioxides.

Other systems. The photostimulated reaction of 1,8-diiodonaphthalene with *p*-methyl-benzenethiolate ions in DMSO yields the substituted cyclized product 10-methylbenzo[*kl*]thioxanthene in moderate yield (Equation 15.12). The mechanism proposed involves an intramolecular radical cyclization after monosubstitution in the propagation cycle of the $S_{RN}1$ process.³⁵

15.3.4.2 5-Exo or 6-Exo Radical Cyclization Followed by a $S_{RN}1$ Reaction

5-Exo trig ring closure. By this approach, 3-substituted 2,3-dihydro-1-*H*-indoles (**29**, Z = *N*-R) and 2,3-dihydrobenzofurans (**29**, Z = O) are easily reached by the versatile application of a 5-*exo* ring closure process during the propagation cycle in the $S_{RN}1$ reaction (Equation 15.13).³⁶

The generation of the aromatic radical, followed by cyclization with a tethered double bond in a 5-*exo* trig fashion afforded a new aliphatic radical that react with nucleophiles by the $S_{RN}1$ mechanism. This radical can be reduced with a hydrogen donor to obtain a reduced cyclized product. The generation and use of a new hydrogen donor, the anion of the dihydro ethyl benzoate reagent derived from nontoxic, reusable, and inexpensive ethyl benzoate was reported for this reaction.³⁷

6-Exo trig ring closure. The tandem 6-*exo-trig* cyclization- $S_{RN}1$ reactions with 1-(but-3-enyloxy)-2-halobenzene and 1-(but-3-enyloxy)-2-halo naphthalenes afford 4-substituted chromanes and benzo[*f*]chromanes **30** in good to excellent yields, in some cases together with the open-chain substitution product (**31**) (Equation 15.14).³⁸ This result agrees with the slower ring closure rate expected for the 6-*exo* cyclization compared with the 5-*exo* process.

Using the same methodology that 5-*exo trig*, the 6-*exo* cyclized product was obtained when the anions of substituted dihydro ethyl benzoates anions are used as hydrogen donors to radicals in liquid ammonia and DMSO.³⁹

15.3.4.3 Intramolecular $S_{RN}1$ Reactions

When a substrate has both the leaving group and a nucleophilic center in an adequate distance, the intramolecular $S_{RN}1$ reaction could afford the ring closure product. The driving force for the ring closure reaction is the large free energy difference between the distonic radical anion intermediate **33**, formed after the C–X bond fragmentation of the radical dianion intermediate **32**, and a conjugated radical anion **34**, formed after the coupling reaction. This radical finally affords the ring closure product **35** (Equation 15.15).

1-Phenyl-indananes and tetralin derivatives. When ω -(2-bromophenyl)alkyl-2-oxazolines **36** were treated with LDA in THF, the anion **36⁻** was formed, and under irradiation afforded the ring closure products 1-phenyl-indanes **37a** ($n = 1$, R = H, 58%), **37b** ($n = 1$, R = Ph, 57%), and tetralin derivatives **37c** ($n = 2$, R = Ph, 50%) (Equation 15.16).⁴⁰

The ring closure of anion **38⁻** occurred via a six-membered ring $S_{RN}1$ -type chain affording dihydro-phenanthrene derivative **39**. In this strongly basic solution, aromatization of **39** affords the oxazolino-phenanthrene derivative **40** in 88% yields. This reaction probably occurs by deprotonation and loss of lithium hydride (Equation 15.17).⁴¹

Under the same experimental conditions, substrate **41** affords, as major product, benzocycloheptane **42** in 44% yield, in which the oxazoline group has undergone a unique areneotropic (oxazoline) migration to the phenyl ring (Equation 15.18).⁴¹

Tetracyclic isoquinoline derivative. The substrate **43** that has an oxazolidinone ring reacts with LDA in THF to form the anion, and under laboratory light, a new fused system **44** is formed in 75% yield in a multistage rearrangement (Equation 15.19).⁴² Two mechanisms involving an $S_{RN}1$ -type process were proposed. EPR spectroscopy and ¹³C-labeling experiment suggested that both were operative.

Aporphine derivatives. The photostimulated intramolecular *ortho*-arylation reactions of bromoarenes linked with pendant phenoxy containing *N*-substituted tetrahydroisoquinolines as **45** in liquid ammonia afford aporphine alkaloid derivatives **46** ($n = 1$) via $S_{RN}1$ reactions, exploiting the bidentate behavior of phenoxide ions that allows obtaining the *ortho*-arylation product in very good yields (Equation 15.20).⁴³

Moreover, tetrahydroisoquinoline precursors that contained EWG groups on nitrogen (i.e., amides, sulfonamides and carbamates) gave cyclized products, whereas precursors with basic nitrogens such as NH failed to afford aporphine skeleton due to a 1,5-hydrogen shift and afforded the aminyl radical. With *N*-Me substitution, aporphine derivative is achieved in low yield (28%) due to an 1,6-hydrogen shift from the *N*-Me group. This strategy was extended for the first time to the synthesis of a homoaporphine alkaloid **46c** ($n = 2$) from **45c** in 40% yield.

Phenanthridine derivatives. The intramolecular arylation of benzylaryl amide ions with a pendant aryl moiety afforded phenanthridine derivatives in very good yields. When amines **47** were treated with *t*-BuOK in liquid ammonia and irradiated, phenanthridines **49** were obtained. The ring closure products were the dihydrophenanthridines **48**, but they were oxidized in the workup (Equation 15.21). Trispheridine, a natural product, was obtained in very good yield (75%).⁴⁴

Benzophenanthridines **50** (from 2-naphthylamine), **51** (from 1-naphthylamine), and the novel naphthophenanthridine **52** (from 2-anthracyl amine) are obtained by following this strategy (Scheme 15.8).

Carbazoles. The synthesis of a series of substituted 9*H*-carbazoles by the photostimulated $S_{RN}1$ substitution reaction using diarylamines as starting substrate was performed through an intramolecular C–C bond formation.

Good conditions for the ring closure reaction via $S_{RN}1$ processes involve the use of 2 equiv. of *t*-BuOK in liquid ammonia to form the anion **53**[−]. After irradiation, good yields of 9*H*-carbazole derivatives **54** were obtained (Equation 15.22). Similar results were found when DMSO was used as a solvent.⁴⁵

SCHEME 15.8 Synthesis of benzophenanthridines and naphthophenanthridine.

With *N*-(2-chlorophenyl)naphthalen-2-amine, *N*-(2-bromophenyl)naphthalen-1-amine and *N*-(2-chlorophenyl)phenanthren-9-amine, the fused carbazoles **55**, **56** and **57** were obtained with good yields (Scheme 15.9).

SCHEME 15.9 Synthesis of fused carbazoles.

Furthermore, when *N*⁴,*N*^{4'}-bis(2-bromophenyl)biphenyl-4,4'-diamine **58** was treated with 4 equiv. of *t*-BuOK in DMSO and irradiated for 90 min, 3,3'-bi(9*H*-carbazole) **59** was achieved in 67% isolated yield (Equation 15.23).⁴⁵

Others fused azaheterocycles. The anion of azaheterocycles, such as pyrrole or imidazole, reacted with ArCl by cathode-induced reactions to give C–C bond formation.⁴⁶ When *N*-(2-iodophenyl)-1*H*-pyrrole-2-carboxamide **60** (1 equiv.) was treated with *t*-BuOK (2 equiv.) in liquid ammonia, anion **60⁻** was formed, and under irradiation the new azaheterocycle 3*H*-pyrrolo[2,3-*c*]quinolin-4(5*H*)-one (**61**) was obtained in 100% yield (Equation 15.24). Product **61** was obtained in 83% yield in DMSO.⁴⁷

Under the same experimental conditions, the anion **62⁻** gives 5*H*-indolo[2,3-*c*]quinolin-6(7*H*)-one (**63**) in 94% yield in DMSO (83% yield in liquid ammonia) (Equation 15.25).⁴⁷

The anions **64⁻** (R = H, Me) derived from pyrazole give under irradiation in liquid ammonia the ring closure products **65**, oxidized in the workup to **66**.⁴⁷ As the nucleus of pyrazole is quite sensitive to light,⁴⁸ it has been suggested that precursors **64** and/or products **65** are partially destroyed by the irradiation. Nevertheless, yields of 54%–56% of fused azaheterocycles **66** (R = H, Me) were obtained (Equation 15.26).

15.3.4.4 Tandem Reactions: S_{RN}1 Intermolecular–S_{RN}1 Intramolecular

The carbazole **69a** could be formed by double S_{RN}1 reactions when 9-aminophenanthrene **67a** reacts with *o*-iodobromobenzene **68a** by a straightforward pathway (Equation 15.27) with 36% yield and the reduced substituted product **70a** (16% yield).¹²

On the other hand, compounds **69b** and **70b** were obtained by reaction of the anion of **67b** with *o*-diiodobenzene **68b** in 35% and 26% yields, respectively (Equation 15.27).

15.4 Other Substrates

15.4.1 Vinyl Halides

Different competitive mechanisms are possible for the nucleophilic substitutions of vinyl halides. The mechanistic route mainly depends on structural features. The vinylic S_{RN}1 is not a common route due to strict competition by other polar routes.

For an exclusive vinylic S_{RN}1 process to take place, not only the substrate structure but also the nature of the anion constituted an essential factor, in addition to an appropriate combination of both. For instance, unambiguous vinylic S_{RN}1 substitutions by carbanions and PhS⁻ ions are known.⁴⁹ A mechanistic study explains the coupling of vinyl radicals with these nucleophiles and the competing H-atom abstraction reactions.⁵⁰

An extension of this work describes more comprehensively the possible competition between ionic and ET routes in nucleophilic vinylic substitution, as well as the reactivity and structure of the vinyl radical intermediate.⁵¹

Competition from a vinylic S_N1 route was excluded when 2-bromo-3-methylbut-2-ene **71** was the substrate, without vinylic or allylic C–H. Under photostimulation, it gives substitution and reduction products by an $S_{RN}1$ process with $\text{Me}_3\text{CCOCH}_2^-$ anion (Equation 15.28). Additionally, the same outcome is observed with other anions such as MeCOCH_2^- , PhCOCH_2^- , O_2NCH_2^- and $(\text{EtO})_2\text{PO}^-$.⁵¹

From the ratios of reduction and substitution products observed in the photostimulated reactions of **71** in DMSO and with the rate of hydrogen abstraction value for radical **71**• in DMSO, the coupling rate constants for radical **71**• with $\text{Me}_3\text{CCOCH}_2^-$, PhS^- , and $(\text{EtO})_2\text{PO}^-$ are 3.9, 1.9, and $0.28 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, respectively. All these values are 50-fold lower than the corresponding k_Y values obtained with phenyl radical, which is due to the a stability difference between the two radicals.⁵¹

Vinyl diethyl phosphate esters (VinDEP) obtained from ketones react under photostimulation with Me_3Sn^- ions in liquid ammonia, affording vinylstannanes via a vinylic $S_{RN}1$ mechanism (Scheme 15.10).⁵² The stereochemical results show that these reactions are stereoconvergent.

These vinylic $S_{RN}1$ reactions strongly depend on the structural features of the vinyl phosphate, and only conjugated vinyl phosphates afforded the substitution product by $S_{RN}1$ reactions.

On the other hand, photostimulated reactions of (diethoxyphosphoryl)oxy-1,3-cyclohexadienes with Me_3Sn^- ions in liquid ammonia affords the corresponding trimethylstannylcyclohexadienes in moderate yields.⁵³ These results represented the first example of vinylic $S_{RN}1$ mechanism without an aryl moiety attached to the vinylic system.

Vinylstannanes can also be obtained in very good yields through the reactions of vinyl chlorides with Me_3Sn^- ions in liquid ammonia by the $S_{RN}1$ mechanism (Equation 15.29).⁵⁴ Substrate **72b** reacts in the dark while substrate **72a** needs photostimulation.

The fact that the reaction affords only one isomer with the same configuration as the starting vinyl chlorides is noteworthy. This indicates an inversion of the vinyl radical intermediate slower than of the coupling reaction with the nucleophile. When the reaction takes place with 1,1-dichloro-1-alkenes, monosubstitution reduced products are formed in an *E/Z* mixture and the reaction becomes stereoconvergent. The vinylstannanes obtained are employed in the synthesis of triarylolefins by Pd-catalyzed cross-coupling reactions with several ArI.⁵⁴

3,3-Difluoro-1-iodo-2-phenyl-cyclopropene (**75**) react with thiolate anions RS^- generated in situ from thiol in DMF in laboratory illumination to give the corresponding substitution products **76** ($\text{R} = \text{Ph}$, 96%; 4-MeC₆H₄, 90%; *t*-Bu, 50%; 3-ClC₆H₄CH₂, 79%) and some amounts of disulfides RSSR (Scheme 15.11).⁵⁵

SCHEME 15.10 Synthesis of vinyl stannanes.

SCHEME 15.11 Reactions of 3,3-difluoro-1-iodo-2-phenyl-cyclopropene **75** with thiolate anions.

15.4.2 Perfluoroalkyl Iodides and Related Compounds

Perfluoroalkyl iodides (R_fI) are able to undergo a variety of nucleophilic substitutions by the $S_{RN}1$ mechanism with different nucleophiles. Some reactions occur in the dark whereas others are accelerated by light. We will only discuss the photostimulated reactions.

The novel compounds Ph_2PR_f ($R_f = C_4F_9, C_6F_{13}$) are synthesized by the $S_{RN}1$ photostimulated reaction of Ph_2P^- ions and R_fI in highly coordinating solvents such as HMPA and DMPU in fairly good yields (68%–85%). The photostimulated reaction of 1,4-diiodoperfluorobutane in HMPA affords the disubstitution product in 55% isolated yield. In tetraglyme, the HME is the main reaction.⁵⁶

It is known that the C–Cl bond in chlorofluorocarbons is usually inert to normal nucleophilic attack, due to the strong EW power of fluorine. However, the thermal reaction of $ArCF_2Cl$ or $ArOCF_2Cl$ with PhO^- and PhS^- ions in DMF or NMP proceeds to give the substitution products in reasonably good yields.⁵⁷ The reactivity of $ArOCF_2Cl$ is lower than that of $ArCF_2Cl$. A S_N2 or a $S_{RN}1$ mechanism can be considered for the reaction.

In these conditions, the reaction between $PhSe^-$ ion and $ArCF_2Cl$ requires visible light irradiation to proceed. The reaction of $PhSe^-$ ion with $ArCF_2Cl$ is performed in DMF at 100°C under visible light irradiation affords $ArCF_2SePh$ in 45% yield.⁵⁷

A photostimulated copolymerization reaction between *bis*-phenol A (**77**) and the dichloride **78** has been carried out to form a novel fluoropolymer **79** that has excellent thermal and solubility properties (Equation 15.30). In the model reaction of **77** with **78** in HMPA at 120°C normally reaches 70% conversion after about 12 h, whereas when the reaction was irradiated by a sunlamp, 70% was obtained in less than 3 h. It is proposed that this polymerization reaction occurs via an unprecedented $S_{RN}1$ mechanism.⁵⁸

15.4.3 Aliphatic Substrates with EWG at the α -Carbon

These substrates comprise α -substituted nitro alkanes, nitrobenzyl and cumyl derivatives, heterocyclic analogues to benzyl, and other $S_{RN}1$ activated compounds. α -Substituted nitro alkanes are probably the most extensively studied substrates in $S_{RN}1$ reactions at an sp^3 carbon.

The activated benzyl chloride **80** reacts with the nitronate anion derived from 5-(hydroxymethyl)-2,2-dimethyl-5-nitro-1,3-dioxane **81** under $S_{RN}1$ reaction conditions to afford the dinitro compound **82** (Equation 15.31).⁵⁹

Under the same conditions, 2-fluorobenzyl chloride gives the desired nitro compound in 31% yield. After reduction of both nitro groups of **82**, the cyclization of amino compounds gives 2-spiroindolines nucleus.⁵⁹

Additionally, nitrobenzo[1,3]dioxole **83** has been shown to react with 2-nitropropane anion to give C-alkylation product **84** by an $S_{RN}1$ mechanism (Equation 15.32).⁶⁰ The best yields are observed in DMSO as solvent.

The reaction was extended to various aliphatic, cyclic, and heterocyclic nitronate anions obtained from commercially available nitroalkanes leading to a new series of nitrobenzo[1,3]dioxole derivatives (13%–69%).⁶⁰

Vanelle, Crozet, and coworkers have reported the $S_{RN}1$ photostimulated reactions of substrate **85** with 2-nitropropyl anion to afford **86** (70% yield) after nitrous acid elimination, and the photostimulated reactions with PhS^- , PhSO_2^- , and $(\text{CO}_2\text{Et})_2\text{CH}^-$ anions to achieve the substitution products **87–89** in good yields (80%–85%) (Scheme 15.12).⁶¹

SCHEME 15.12 Reactions of 6-halo-2-(chloromethyl)-3-nitro-2,3-dihydroimidazo[1,2-a]pyridine **85** with different nucleophiles.

From the 6-halo-3-nitroimidazo[1,2-a]pyridines **89** bearing the diethyl methylmalonate group, new tricyclic pyridinones are synthesized.⁶² Further tricyclic pyridinones such as **91** are obtained from **90** as the starting substrate (Equation 15.33).⁶³ The synthesis involves four steps with a Suzuki-Miyaura cross-coupling reaction and a direct olefination with diethyl ketomalonate as key steps.

A series of nitronate and malonate anions reacts only at the chloromethyl group at the 2-position of **92** in DMSO under photostimulation (Scheme 15.13). The reaction with nitroalkane anions gives the ethylenic derivatives resulting from the consecutive C-alkylation and nitrous acid elimination. A $S_{RN}1$ mechanism is confirmed to take place in these reactions and in the reactions with the diethyl malonate anions (Scheme 15.13).⁶⁴

SCHEME 15.13 Reaction of 6,8-dibromo-2-(chloromethyl)-3-nitro-2,3-dihydroimidazo[1,2-*a*]pyridine **92** with different nucleophiles.

On the other hand, when the reaction of **92** is carried out with conventional S-centered anions, it does not follow a free radical chain mechanism exclusively, and a nucleophilic substitution displacement is also operating. Moreover, with PhS^- anion, the main product observed is that from the replacement of bromide atom at the 8-position and chloride atom on the chloromethyl group at 2-position of **92**.⁶⁴ In this case, the 8-position reacts only via free radical chain reaction, and the chloromethyl group can follow borderline mechanisms between $\text{S}_{\text{N}}2$ and $\text{S}_{\text{RN}}1$.

Recently, a $\text{S}_{\text{RN}}1$ reaction on nonnitrated heterocycle system has been described for the first time.⁶⁵ The new 3-bromo-2-(chloromethyl)-4*H*-pyrido[1,2-*a*]pyrimidin-4-one reacts with 2-nitropropane anion under photostimulation to give the ethylenic derivative **93** resulting from the consecutive C-alkylation and nitrous acid elimination (Equation 15.34).

The reaction of **93** with C-centered nucleophiles is through the $\text{S}_{\text{RN}}1$ mechanism. However, with S-centered nucleophiles, the reaction seems to follow a $\text{S}_{\text{N}}2$ mechanism.⁶⁵

The reaction of 2,3-*bis*(chloromethyl)-1,4-naphthoquinone with 2-nitropropane anions proceeded by two consecutive $\text{S}_{\text{RN}}1$ reactions leading to a *bis*-C-alkylated product.⁶⁶ Extension of this *bis*- $\text{S}_{\text{RN}}1$ reaction to various nitronate and malonate anions and S-centered anions led to a new class of potentially active benzo[*g*]quinoxaline-5,10-dione derivatives. These compounds are part of a group of bioreductive *bis*-alkylating antitumor agents.

From the 1,4-naphthoquinone **94** obtained by an intermolecular photostimulated $\text{S}_{\text{RN}}1$ reaction, a new naphthoquinonic alkylating agent **95** is synthesized.⁶⁷ The photostimulated reaction of substrate **95** with sodium methoxide in methanol allows the formation of the cyclopentanaphthalenedione **96** by an intramolecular $\text{S}_{\text{RN}}1$ cyclization (Equation 15.35).

Furthermore, a series of highly functionalized quinones were prepared by the reaction of 2,3-*bis*(chloromethyl)-1,4-dimethoxyanthraquinone with various nitronate anions under ET reaction conditions.⁶⁸ The reaction proceeded according to *bis*- $\text{S}_{\text{RN}}1$ mechanism.

α -Halocarbonyl compounds are the other type of activated aliphatic compounds bearing EWG at the α -carbon employed as substrates for $S_{RN}1$ reactions. For instance, by the reaction of **97** with 2-nitropropyl anion, the ethylenic α,β -unsaturated ketones **98** is obtained via nitrous acid elimination from the C-alkylation intermediate (Equation 15.36). With 2-bromo-1-(4-nitrophenyl)ethanone, ethylenic α,β -unsaturated ketone is obtained in 90% yield.⁶⁹

This reaction was extended to cyclic nitronates to synthesize several unknown α,β -unsaturated ketones, which are useful key intermediates bearing the well-known chalcone pharmacophore.

By a simple method, the conversion of aromatic aldehydes to their corresponding phosphates can be achieved.⁷⁰ In addition to their biological interest, these esters can be used in further synthetic transformation. Thus, the photostimulated $S_{RN}1$ reaction of phosphate **99** with nitroethylcyclohexene **100** and *t*-BuOK affords the new nitro derivative **101** in 56% isolated yields (Equation 15.37).

15.4.4 Cycloalkyl, Bridgehead, and Neopentyl and Related Halides

15.4.4.1 Cycloalkyl Halides

2-Haloadamantanes (2-AdX) can be considered halocyclohexanes with an even lower reactivity toward nucleophiles than 1-AdX or the simple halocyclohexanes. In the photostimulated reaction of 2-AdI with carbanions derived from acetophenone (62%), 2-naphthyl methyl ketone (32%), *N*-acetylmorpholine (32%), and anthrone (37%), substitution is achieved. The reaction with PhCOCH₂[−] anion induced by FeBr₂ affords 88% yield of substitution product. Nitromethane anion is unreactive under irradiation, but in the presence of Me₃COCH₂[−] anion as entrainment reagent, 88% yield of substitution is furnished.⁷¹

Recently, the synthesis of new 1,1-bis(trimethylstannyl)cyclopropanes by the $S_{RN}1$ mechanism has been reported.⁷² 1,1-Dichlorocyclopropanes react under irradiation with Me₃Sn[−] anion in liquid ammonia to give the disubstitution products bis-stannylcyclopropanes in good to excellent isolated yield (Scheme 15.14). The starting dichlorocyclopropanes are easily obtained by the addition of dichlorocarbene to alkenes.

SCHEME 15.14 Synthesis of 1,1-bis(trimethylstannyl)cyclopropanes by the $S_{RN}1$ mechanism.

15.4.4.2 Bridgehead Halides

Bridgehead halides have a high-energy barrier for a polar mechanism owing to strain factors. Many of these halides have been found to react by the $S_{RN}1$ mechanism.

The photostimulated reaction of 1-haloadamantane (1-AdX, X = Br, I) and 2-AdBr with nitromethane anions gives good yields of the substitution product 1-AdCH₂NO₂ and 2-AdCH₂NO₂, respectively, in the presence of the enolate anions of acetone (entrainment conditions) in liquid ammonia.⁷³

1-AdI reacts under photostimulation in DMSO with primary nitroalkane ions in the presence of acetone enolate anion to give the substitution products 1-AdCHRNO₂ in very good yields (77%–85%). With secondary nitroalkane ions, the yield of 1-AdCR₂NO₂ (R=Me, 17%) is modest.⁷⁴

Furthermore, 1,3-dibromoadamantane reacts under irradiation with NO₂CH₂[−] and Me₃COCH₂[−] anions (entrainment reagent) to give the disubstitution product in 84% yields.⁷³ On the other hand, under the same conditions, the reaction of 1,4-dibromoadamantane with NO₂CH₂[−] and MeCOCH₂[−] anions under irradiation renders the monobromo-substitution products (32%) and the disubstitution product (47%).⁷³

Cyanide ions react in a photostimulated reaction (254 nm) with 1,3,5,7-tetrabromoadamantane **102** in DMSO, affording the tetrasubstituted product 1,3,5,7-tetracyanoadamantane **103** in 73% yield by the $S_{RN}1$ mechanism (Equation 15.38).⁷

The photostimulated reaction of the iodo ketone **104** in DMSO affords the rearranged substitution product **107** (83% yield). The ET to **104** followed by iodine elimination furnishes the bridgehead radical **105**. This radical rearranges quite fast by a 1,5-hydrogen shift to afford the methylene radical **106**, which couples with Ph₂P[−] ions to yield the observed substitution product **107** after oxidation (Equation 15.39).⁷⁵

The increased reactivity of π -substituted versus unsubstituted alkyl halides in ET-catalyzed nucleophilic substitutions ($S_{RN}1$) has been explained, within the stepwise scheme, by an intramolecular π catalysis or within the dissociative-concerted framework by the study of anionic species in which the π and σ subsystems are separated by aliphatic bridges of different flexibility using DFT functionals.⁷⁶ The reductive cleavage of these compounds is controlled by the rigidity of the polycyclic structure, its capability to form an unstrained radical, and by the relative C=O/C–Cl disposition on the bridge. Such control can be exerted by either a concerted-dissociative or a stepwise mechanism with radical anions as intermediates.

15.4.4.3 Neopentyl and Related Halides

Neophyl iodide **108** reacts under irradiation with PhCOCH₂[−] anions to afford the straightforward and rearranged substitution compounds **109** (50%) and **110** (16%) in moderate yields (Equation 15.40).⁷⁷

Although the overall quantum yields determined for the reactions studied are below unity, the chain lengths ($\Phi_{\text{propagation}}$) for the reaction of **108** with PhCOCH_2^- and NO_2CH_2^- anions are 127 and 2, respectively. For the first time, the $\Phi_{\text{propagation}}$ for a $\text{S}_{\text{RN}}1$ process was measured.⁷⁷

Disubstitution at aromatic and aliphatic sites is achieved by the photostimulated reaction of pinacolone and acetophenone ion with 2-(4-halophenyl)-2-methyl-1-chloropropane **111** (Equation 15.41).⁷⁸ In DMSO, the main reaction is the $\text{S}_{\text{RN}}1$ nucleophilic substitution to afford disubstitution **112**, rearranged disubstitution **113**, or reduction at the aliphatic ($\text{C}_{\text{sp}^3}\text{-Cl}$) one. In liquid ammonia, the main reaction is only substitution at the aromatic C-halogen site to yield **114**.

16.1 Introduction

Aryl halides have an important role in photochemistry since a long time. Historically, studies of the phosphorescence of aromatics and of their halogenated derivatives have been instrumental in defining the modern concept of triplet state, and both the intersystem crossing [1] and the fragmentation of phenyl halides have been long known [2]. In the early years of these studies, attention was given more often to photophysics than to photochemistry. This is because the introduction of electron-withdrawing substituents, such as halogen atoms, in the ring further increases the already high stability of aromatic compounds, both in the ground and excited states. Indeed, many aromatic compounds are quite photostable and the absorption of a photon leads to reemission rather than to reaction, since excitation causes only a partial decrease of the bonding character in the multiple π -electron array of such compounds and the rigid σ -bond skeleton disfavors geometric modifications. Indeed, stability to chemical agents and to irradiation is characteristic of many aryl halides, and this family includes some notoriously persistent environmental pollutants, such as DDT and polychlorobiphenyls. However, photochemistry, albeit often inefficient, is one of the few available paths for the degradation of such compounds and thus this is

an important topic in environmental studies. Furthermore, new discoveries are revealing new reactions and a more various palette of transformations is forming for aryl halides, as a part of the development of the studies on aromatics that form a fast growing field in contemporary photochemistry.

Many reviews on this topic are available in the literature [3–8]. In particular, two excellent accounts by a specialist in the field, Nigel J. Bunce, have been devoted to the most important photochemical reaction of these compounds, dehalogenation, and have been published in the previous editions of this handbook (1995, 2004) [3,4]. Adopting the same pattern, the discussion in this chapter will be grouped in broad mechanistic categories. It has been attempted to review all of the main processes, but certainly not all of the examples that are being published at an increasing pace. Preference has been given to the most recent reports.

16.2 Effect of Halide Substituents on the Photophysical Parameters of Aromatics

Aromatic compounds often exhibit recognizable fluorescence and phosphorescence, as well as transient absorptions upon flashing and have thus always formed a favorite hunting field of photophysics. An important part of these studies involves halogen derivatives that are available through synthetically easy procedures. The effect caused by the introduction of a halide depends first of all on its nature, since, as it is well known, heavy atoms weaken spin exclusion rules. The introduction of a halogen on the ring produces a large effect since the halogen lays directly on the π -system involved in the electronic transition. As a result, the direct generation of T_1 by light absorption becomes more likely (e.g., the $S_0 \rightarrow T_1$ band is visible in the spectrum of *p*-iodotoluene, $\epsilon \sim 0.5 \text{ mol}^{-1} \text{ cm}^{-1}$) [9] and both $S_n \rightarrow T_m$ and $T_1 \rightarrow S_0$ intersystem crossing rates increase. This results in a shortening of the lifetimes of both singlet and triplet states proportionally to the atomic weight [10].

Both fluorescence and phosphorescence are observed, in some cases with further differentiations. As an example, chlorobenzene exhibits a dual phosphorescence in matrix. The two components have been attributed to emission from T_1 , a $\pi\pi^*$ state, for the slow one and from T_{11} , a bound, though strongly deformed, $\sigma\pi^*$ state, for the fast one [11,12]. In the case of bromobenzene, the high rate of homolysis further shortens the triplet lifetime and makes emission in a conventional matrix difficult to observe. This is possible, however, in a highly viscous matrix, such as that formed by glycerol or 3-methyloctane [11]. Fluorobenzene is also nonphosphorescent, but a transient T-T spectrum has been detected in solution ($\tau \sim 0.7 \mu\text{s}$ in cyclohexane) [11]. When passing to naphthyl halides or higher aromatics, emission is more intensive. In particular, 1-bromonaphthalene and derivatives are among the few organic compounds for which room temperature phosphorescence is known (see the following). Furthermore, the triplet states of naphthyl halides have been extensively studied by flash photolysis and transient electron paramagnetic resonance (epr) spectroscopy [13,14].

The heavy atom effect on emission is position dependent. As an example, the phosphorescence lifetime for chlorophenanthrenes (in EPA at 77 K) ranges from a maximum of 2.47 s for the 2-substituted derivative to a minimum of 0.32 s for the derivative in 9 (0.197 and 0.0108 for the corresponding bromophenanthrenes, 0.0271 and 0.00173 for the iodophenanthrenes) [15, Chart 16.1].

^a See Ref. [17].^b Solid adducts with trimeric perfluoro-*ortho*-phenylene mercury, room temperature [17].^c See Ref. [18].

A synergism between internal and external heavy atom effect has been evidenced both as a shortening of the emission lifetime and as a decrease in reactivity, for example, in adducts with a strong field-perturbing agent such as TINO₃ [16]. In Table 16.1 the phosphorescence lifetimes of naphthalene and its halogenated derivatives in EPA matrix at 77 K are gathered and compared with those from the solid 1 to 2 adducts with a trimeric perfluoro-*ortho*-phenylene mercury derivative [17, see Chart 16.2]. It can be seen that the external effect is more important and reduces the span between the halogen derivatives, which is still appreciable however. The relative rates of dehalogenation [18] are also reported. These increase with the halogen atom weight, since the aryl-X bond is weakened (see Section 16.4), but decrease when the external atom effect shortens the triplet lifetime.

Phosphorescent solid state complexes have important applications, as an example for organic LEDs (OLEDs).

The aforementioned room temperature phosphorescence has found important applications in analytical chemistry. In general, enhanced phosphorescence has been obtained by inhibiting the quenching of triplet states through the use of an organized medium or by rigorously excluding oxygen. Derivatives of 1-bromonaphthalene are a favorite probe for studies on this topic that have been reviewed [19]. Inclusion in cyclodextrins makes phosphorescence well detectable arriving at a lifetime in the microsecond range [16,20]. Cyclodextrin enhancement is preferred in analytical chemistry because of the easy sample preparation (no bubbling in the solution required) and high sensitivity. In cyclodextrins, formation of excimers has been likewise revealed through the typical structureless emission [21,22]. In particular, a 1 to 1 and different 2 to 2 complexes are formed in γ -cyclodextrin under neutral and basic conditions [21]. Ternary complexes involving 1-bromonaphthalene, β -cyclodextrin, and cyclic aliphatic compounds such as cyclohexane, piperidine, and 1-ethylpiperidine are particularly effective in enhancing the emission [23]. This phenomenon has been exploited for the determination of such aliphatic compounds, also in an enantioselective way, based upon the well-known sensitivity of the fluorimetric method [24].

**CHART 16.2**

As for the bimolecular interactions of excited states, introducing a halogen atom has usually a modest effect on such processes. As an example, fluorobenzene behaves as a normal energy donor and sensitizes the *E/Z* isomerization of 2-butene [25]. Likewise, the process of oxygen sensitization by halobiphenyl or halonaphthalene fits, with regards to rate and efficiency, in the same general frame as halogen-free aromatics in a model based on charge transfer and noncharge transfer paths [26].

16.3 General Scheme of Photoreactivity

In several cases, a fluoro or chloro atom substituted in an aromatic ring behaves as an innocent bystander, introducing no new chemistry. This is certainly the case when a fast reaction not involving the aromatic moiety occurs. An example is the rotation around the double bond in the overcrowded diarylalkene shown hereafter (27, Scheme 16.1). Here, the halide can be used as an inert marker.

In the other cases, when the photochemistry involves the aromatic ring, the reactions may be distinguished into two groups, those that are characteristic of the aromatic ring per se and are affected in some way by the substituent (see Section 16.4) and those involving the aryl-halide bond (see Sections 16.5 to 16.8). The latter group includes first of all unimolecular processes, viz. both homo- (path a) and heterolytic (path b) cleavage, either of which takes place depending on structure and conditions (Scheme 16.2).

SCHEME 16.1

SCHEME 16.2

The first one leads to the phenyl radical and most often to reduction, the latter one to the phenyl cation, the chemical behavior of which depends on the multiplicity and leads either to reduction (b') or to substitution (b''), $\text{ArS}_{\text{N}}1$.

Alternatively to the aforementioned processes, a variety of bimolecular reactions may occur. Formation of an exciplex with some donor (path c) followed by trapping by an electrophile HY is another mechanism for reduction. With a better donor, for example, an enolate, or when the halide bears an electron-withdrawing substituent, electron transfer (path d) takes place. This is followed by halide loss from the radical anion leading again to the phenyl radical and eventually to reduction (d'). In this process, as mentioned before, a strong donor (usually an anion) is necessarily present; in a following step, this may combine with the radical and initiate a chain substitution reaction (path d'', $\text{ArS}_{\text{RN}}1$ process). A mirror-like mechanism leading to the radical with reversed roles is also conceivable (path e). Attack to the excited state and substitution via an addition-elimination process, just as in the ground state reactions is another possibility ($\text{ArS}_{\text{N}}2^*$, path f).

16.4 Photochemical Reactions Not Involving the Carbon-Halogen Bond

16.4.1 Rearrangement

Rearrangement and cycloaddition are the typical photochemical reactions of benzene and many of its simple derivatives and generally involve the singlet state. The increased intersystem crossing in aryl halides leads to the expectation that such processes are not favored among these compounds. However, many examples are known, although demonstrating their occurrence is not always trivial. As an example, the isolation and identification of a rearranged product such as benzvalenes is not experimentally simple, since this is a reversible process. Therefore, one may use an indirect indication that witnesses the reversible rearrangement, such as the positional isomerism in polysubstituted benzenes or the trapping by trifluoroethanol of the intermediate prefulvene (a diradical or zwitterion) to give a bicyclo[3.1.0]hexyl trifluoromethyl ether. The formation of such ethers is observed in many simple derivatives, but not, for example, in fluorobenzene, for which, on the other hand, there is little room for a chemical reaction from the singlet, since the sum of quantum yield of fluorescence (0.11) and the quantum yield of intersystem crossing (0.80) is close to 1 [28–30]. Thus, a reversible rearrangement to a bicyclic intermediate does not occur significantly in solution, or at least the equilibrium concentration of the intermediate is quite low [28]. Things may be different in a matrix at low temperature, at least for some derivatives. In fact, some new IR absorptions developing when hexafluorobenzene is irradiated at 193 nm in matrix suggest that rearrangement to perfluorobenzvalene occurs [31]. On the other hand, when irradiated at 254 nm in the vapor phase, hexafluorobenzene and some other heavily fluorinated derivatives give the corresponding Dewar benzene in a good yield [32,33, Scheme 16.3].

SCHEME 16.3

16.4.2 Cycloaddition and Addition

Probably the most useful photoreaction of aromatics is the photocycloaddition with olefins. In this reaction, fluoro- and chlorobenzene generally conform to the same pattern as the parent molecule. The ionization potential of these compounds only slightly differs (respectively 9.20 and 9.10 eV vs. 2.25 eV for benzene) and the generalizations that have been formulated for the preferred mode of reaction (*meta* cycloaddition when the benzene/olefin IP difference is between 0 and 1.6 eV, *ortho* when this is larger [34]) lead practically to the same predictions. Thus, *meta* cycloaddition is expected with aliphatic alkenes or cyclooctene, *ortho* cycloaddition (followed by a [4 + 2] reaction) for maleic anhydride and maleic and fumaric acid [35]. In fact, the *meta* cycloaddition reaction does take place with both fluoro and chlorobenzene with 1,2-dichloroethene, in the first case giving a 1-to-1 mixture of the two regioisomers, in the latter one a single regioisomer in 50% yield [31,33, Scheme 16.4]. An accompanying process is arylation. With cyclopentene, chlorobenzene mainly gives stereoisomeric phenylchlorocyclopentanes or phenylcyclopentene by dehydrohalogenation of the former compounds. Bromobenzene (and possibly iodobenzene) behave analogously (see further Section 16.5). On the contrary, with fluorobenzene *meta* and *para* cycloadducts are the main products, with a minor contribution of insertion [36, Scheme 16.4]. With this compound a nonselective *meta* addition occurs also with vinyl acetate [37] and a mixture of seven products has been obtained with furan [38]. On the other hand, this is not peculiar of aryl halides, but rather a general limitation of the benzene–olefin cycloaddition, which in fact is synthetically useful in the intramolecular version, when the preferred conformation drives the regioselectivity.

Again hexafluorobenzene behaves differently and undergoes efficient 2 + 2 cycloaddition with alkenes [39], giving products susceptible of synthetically interesting elaboration. With benzene pentafluorobiphenyl is formed and with toluene a mixture of methyltetrafluorobiphenyls [40], perhaps via exciplex rather than via radicals.

With primary and secondary amines chloro and fluorobenzene undergo both addition to give all the possible halo-2,4-cyclohexadienylamines (in some cases the 2,5-cyclohexadienyl derivatives) and substitution to give the anilines, the latter products arising via an addition–elimination path. These reactions appear to arise from the singlet state and the halogen atom decreases the quantum yield of reaction,

SCHEME 16.4

SCHEME 16.5

SCHEME 16.6

SCHEME 16.7

presumably because it stabilizes an exciplex intermediate, but has little effect on the regioselectivity [41,42, Scheme 16.5]. With tertiary amines α -cyclohexadienylamines are obtained.

With highly condensed aromatics the introduction of halogen atoms does not change the photoreactivity pattern of the hydrocarbon. As an example, the typical 4 + 4 photodimerization in the anthracene series is maintained. Thus, 9-bromoanthracene gives the head-to-tail dimer effectively. The product has proven suitable for the (radical photoinitiated) preparation of vinyl polymers labeled with an aromatic nucleus [43, Scheme 16.6].

Chloro and fluoronaphthalene undergo 4 + 4 cycloaddition with 5-fluorouracil, in the former case predominantly onto the substituted ring, in the latter one in a ca. 1-to-1 proportion between the two regioisomers [44, Scheme 16.7].

16.5 Homolysis

16.5.1 Mechanism

Electronic excitation is a way for activating the aryl-halide bond. The lowest singlet state reactions are geometrically modified with respect to the ground state. Loss of ring planarity leads toward ring rearrangement (see Section 16.4), but hinders labilization of the peripheral aryl-halide σ bond. This seems not to be the case for triplet states, more close to planarity and where both homolytic and heterolytic

SCHEME 16.8

cleavages are possible. Most investigations identify homolysis in the triplet state as the mechanism for the dehalogenation of simple benzene derivatives. This is in contrast with what is established for vinyl halides that most often undergo heterolytic cleavage. It has been suggested that the difference, somewhat surprising in view of the close similarity of the two moieties and the analogous thermochemistry of the two processes, may reside in the different geometry (linear in the first case, necessarily bent in the latter one). This allows for stabilization by substituents directly on the charged carbon only with the vinyl cation [45, Scheme 16.8]. In the scheme it is indicated how a methyl, a vinyl, and a phenyl group stabilize a vinyl cation through the in plane interaction of orbitals, while this is not possible for the phenyl cation.

However, recent studies have progressively revealed that substituents and conditions may make heterolysis the predominating path also among aryl halides (see Section 16.8).

The C–Cl bond dissociation energy of chlorobenzene, which has been estimated experimentally and through calculations at various levels around 390 kJ/mol, is limitedly affected by introducing substituents on the ring [46]. DFT calculations at the B3LYP/6-31G** level have shown to be an excellent method for the prediction of the BDE in compounds of this type [47]. It results that dissociation from the lowest triplet is only moderately endothermic. Fragmentation from T_1 is favored for bromobenzene (and a fortiori iodobenzene), while is impossible, and is not observed, for the fluoro derivative (see Table 16.2).

16.5.2 Unimolecular Fragmentation in the Gas Phase

Thermochemical considerations establish a *sine qua non* condition, but are not sufficient for the definition of the mechanism, which at any rate depends on conditions. Many investigations have been devoted to the determination of the detailed path. The problem is the lowest excited states (both singlet and triplet) are of $\pi\pi^*$ type (except for iodides) and thus not directly involved in the fragmentation of the σ_{C-X} bond, as demonstrated in the case of chlorobenzene by multireference CASSF second-order perturbation theory (MSCASPT2) calculations [11].

In the gas phase, the intervention of upper states is possible and appropriate techniques allow to determine the photodissociation dynamics parameters (for a review see [48]). Thus, a study carried out by using femtosecond pump probe spectroscopy (266 nm) combined with time-of-flight spectroscopy has revealed two fast dissociation paths for iodobenzene (lifetime 350 and 700 fs) and less fast paths for bromobenzene (28 ps) and chlorobenzene (1 ns) [49]. A further study on chlorobenzene has demonstrated that the path followed depends on the excitation energy, as experimentally observed and

CHART 16.3

computationally rationalized. Irradiation at 193 nm brings up to S_4 (Chart 16.3). Three channels leading to dissociation are accessible in this case, viz. directly from S_4 , a $\pi\sigma^*$ state, via bound S_3 that intersystem crosses to repulsive T_5 , also a $\pi\sigma^*$ state, or through a hot ground state reaction. Only the last path is accessible by irradiation at 266 nm [11, Chart 16.3].

Bromobenzene likewise cleaves via the triplet, S_1 is a bonding $\pi\pi^*$ state that intersystem crosses to a repulsive $\pi\sigma^*$ triplet (T_4). Iodobenzene has a fast channel directly from S_1 , a repulsive $\pi\sigma^*$ state, and a slow one via bonding S_2 that couples with repulsive triplets. As for fluorobenzene, short wavelength (248, 193, 157 nm) irradiation causes HF elimination, a process that appears to involve the vibrationally excited ground state formed by internal conversion [50].

When more halogens are present, the rate of homolysis can be affected to a large extent (obviously the weakest bond is cleaved when different halides are present). Thus, introducing a single fluorine atom in bromobenzene has little effect on the rate, but two or more drastically reduce the lifetime. The observed behavior has been correlated to the calculated relative location of $\pi\pi^*$ and $\pi\sigma^*$ states [51]. On the contrary, the dissociation of polybromobenzene is slower than that of the monosubstituted derivative, e.g., it decreases by a factor of 15 from bromobenzene to 1,3,5-tribromobenzene [52].

16.5.3 Fragmentation in Solution and in Matrix

In an inert matrix (Ar at 10 K), iodobenzene undergoes homolytic cleavage (see further Section 16.8). In solution, relaxation is faster and fragmentation generally involves the lowest triplet. Bimolecular interactions may affect the unimolecular cleavage rate, however. As an example, the photofragmentation of chlorobenzene in solution is quite efficient (Φ_r ca. 0.5 in cyclohexane) at a low concentration ($<10^{-3}$ M), but much less in concentrated solution, due to the formation of an exciplex that is chemically less reactive than nonassociated T_1 [53, Scheme 16.9] (notice however that in other halides, e.g., in biphenyls, the cleavage is more efficient in the exciplex). During the process a considerable amount of chlorocyclohexane is formed. This results from the photosensitized addition of hydrogen chloride on cyclohexene, in turn arising from the disproportionation of the cyclohexyl radical [54].

In oxygen-equilibrated solution the phenyl radical is trapped by oxygen and the resulting phenylperoxy radical has been likewise detected by flash photolysis [55]. In polar media substitution competes with reduction, as an example, in alcohols, ethers are also formed. It has been suggested that the primary

SCHEME 16.9

SCHEME 16.10

photoprocess remains homolysis, but electron transfer within the radical pair leads to the phenyl cation and the latter is the intermediate in the solvolysis. This may be true, but under these conditions, adding an alkene leads to the characteristic arylation typical of triplet phenyl cation (see Section 16.8), the occurring of which would be ill reconciled with such a mechanism (that would involve the singlet). Alternative possibilities are that an exciplex with the alkene has a role [56] or that relatively acid solvents drive the system toward the aryl cation (Scheme 16.10).

The reduction/substitution competition and the underlying mechanisms are subject to many variations, however. Notice further that the ratio reduction vs. substitution has been found to depend not only on the medium but also on the temperature [57].

As for polyhalogenated aromatics, the irradiation of a variety of poly(bromo, chloro)benzenes has given a mixture of dehalogenated products, biphenyls, and terphenyls (Scheme 16.11). Some generalizations have been obtained. Thus, in chloro derivatives, a chlorine not flanked by further chlorine atoms is more easily photoactivated than one flanked by one and still more by two of them, while the reaction of polybromoderivatives is less selective. When both Cl and Br are present, bromine is always preferentially lost [58]. It has been noticed that the photoreduction of hexachloro to pentachlorobenzene is accompanied by a considerable increase of the stable carbon isotope ratio [59].

The relatively high aryl-halide bond dissociation energy (see Table 16.2) explains the fact that photohomolysis is not a viable path from higher aromatics, or at least not from the lowest excited states, which are considerably more stabilized than in the benzene series. On the other hand, higher states may intervene. In 9-bromo and 9,10-dibromoanthracene the S_1 state ($\pi\pi^*$) exhibits no photoreactivity either in fluid or in matrix at 80 K, but under the latter conditions fluoresces strongly. As for photoreaction, this occurs only under short-wavelength irradiation and leads to debromination but with a quantum yield that depends on conditions (up to 0.1). The occurring of the reaction in fact requires two conditions, viz.

SCHEME 16.11

SCHEME 16.12

the intervention of a high-lying state (here C–Br homolysis occurs via the S_2 state of $\pi\sigma^*$ nature) and that the fast recombination of the primarily formed radicals is avoided, the latter process depending on viscosity and temperature [60, Scheme 16.12].

The weakness of the aryl–iodide bond makes deiodination a viable path also for higher aromatics, however. Thus, irradiation of samples of poly(methyl methacrylate) or polystyrene containing iodonaphthalene and iodophenanthrene leads initially to phosphorescence of the iodide, but then a change in the emission shape intervenes and has been attributed to the formation of photoproducts [61].

16.5.4 Assisted Photoreduction

An alternative to the aforementioned unimolecular cleavage is donor-assisted photoreduction. Smooth dehalogenation of chloro and bromoaromatics via an exciplex takes place with aliphatic amines, much more efficiently with secondary (that provide the hydrogen atom) than with tertiary amines [62, Scheme 16.13].

Another example of dehalogenation via exciplex that has been studied in detail involves dichloroanthracene and dienes, which form an exciplex irrespective of the nature of the solvent. Subpicosecond investigation reveals, however, a differentiation in the ensuing course of the reaction. Indeed, the end result is photocycloaddition in apolar media, but reductive dechlorination in polar media. With 2,5-dimethyl-2,4-hexadiene this has been demonstrated to be a kinetically complex phenomenon where the singlet excimer, a terplex and the radical anion are involved. The last intermediate appears to be protonated and then to give the final product, monochloroanthracene, via disproportionation or chloride loss, rather than undergoing initial dechlorination to give the anthracenyl radical [63,64, Scheme 16.14].

Both the exciplex and the terplex appear to dechlorinate with about the same efficiency, whereas the latter intermediate does not react in the analogous reaction with *N*-methylaniline [65]. 1-Bromonaphthalene and some of its derivatives, 9-bromophenanthrene and 2-bromodibenzofuran, are cleanly photoreduced upon irradiation in *iso*-propanol in the presence of bases, the hydroxide ion serving as the electron source [66, Scheme 16.15].

SCHEME 16.13

SCHEME 16.14

SCHEME 16.15

In the case of 1-chloropyrene, dechlorination occurs also under assistance by cyanide ion [67]. Dehalogenation may be important in laser ablation. In this technique the effect (cavitation) is caused either by local heating and boiling of the liquid or by a photochemical reaction. The latter appears to be the case for polymers doped with iononaphthalene [61].

16.5.5 Other Reactions

In nonreducing solvents, photochemical activation leads to isomers of the starting halides (Scheme 16.16). Di-, tri-, and tetrachlorobenzene undergo migration of the halogen atom, preferentially to the *meta* position, a reaction that has been rationalized as the result of homolysis and radical recombination at the position with the largest spin. A clean reaction has not been obtained, however, and positional isomerization, reduction, and aryl-aryl coupling all occur to some degree [68,69]. Likewise, chlorobiphenyls in water undergo reductive dechlorination, substitution, and isomerization [70,71].

Furthermore, biphenyls are formed through solvent trapping upon irradiation of aryl halides in neat benzene. Indeed, this is the exclusive process by irradiation of *o*-dichlorobenzene in benzene [68].

16.6 Reactions via the Radical Anion

Electron transfer is a common occurrence in photochemistry and the relatively easy reduction of aryl halides offers another access to phenyl radicals via electron transfer and cleavage of the radical anion. Indeed, this is a topic with most synthetic applications. The chlorobenzene radical anion is extremely

SCHEME 16.16

unstable in the gas phase and under such conditions it seems appropriate to conceive electron transfer and dissociation as synchronous steps [72], although in solution a stepwise mechanism operates [73,74].

16.6.1 Nonchain Processes

A number of inter- and intramolecular cases are known. The intermolecular reactions are exemplified by that of 4-chlorobenzonitrile with 1,1-diphenylethylene, where reductive elimination of the chloro atom produces the 4-cyanophenyl radical that in turn couples with the alkene radical cation [54, Scheme 16.17]. The process is terminated by solvent addition to the carbocation site. Intramolecular cases have likewise been reported. The irradiation of 2'-(chloro or bromo)benzanilide gives, besides photo-Fries rearrangement and cyclization to phenanthridone, reduction and cyclization to the phenylbenzoxazole. The last product, which is more abundant with the bromo derivative in the presence of NaOH, has been attributed to the dehalogenation from the radical anion formed by intramolecular electron transfer (compare Section 16.8) [74,75].

16.6.2 Chain Processes

The situation changes when some additional conditions are fulfilled. These are that the radical forms quite easily (that is the aryl-halide bond is weak) and the nucleophile is so strong that it reacts with aryl radical in the ground state. Under such conditions, a radical chain process sets in (Scheme 16.18). This is the $S_{\text{RN}}1$ reaction, typical of aryl iodides (though sometimes observed with different halides) with good donors such as enolates (functioning both as donors in the initiating step and as addends in the chain

SCHEME 16.17

SCHEME 16.18

SCHEME 16.19

process). Differently from the previous case, this process, which is discussed in detail elsewhere in this handbook, often occurs with a reaction quantum yield $\Phi_r \gg 1$.

16.7 $\text{ArS}_\text{N}2^*$ Substitution Reactions

$\text{ArS}_\text{N}2^*$ nucleophilic substitutions have a peculiar role in photochemistry, because the observation by Havinga that such a process is activated by a nitro group in *meta* position has been one of the key observations that initiated the rationalization of molecular photochemistry based on the electronic structure. The reaction follows the same pattern as the thermal $\text{ArS}_\text{N}2$ reaction, but the excited state is an electronic isomer of the starting material and the regiochemistry changes (Scheme 16.19). Thus, 3-fluoronitrobenzene is more readily converted to 3-nitrophenol than the isomers in 2 and 4 (though this characteristic does not extend to the chloro and bromo analogues) [76]. With an amine as the nucleophile, nitro group reduction predominates over substitution in the benzene series, but the latter reaction takes over with naphthalenes [77]. The irradiation of 1,2-dichlorobenzene in trimethyl phosphite has been reported to give a mixture of the mono- and di-substituted products [78].

16.8 $\text{ArS}_\text{N}1$ Arylation Reactions

The heterolytic cleavage of an aryl-halide bond in the gas phase is energetically unattainable. However, this path is viable for electron-donating substituted aryl halides in polar media (see Table 16.3). In particular, B3LYP calculations evidence that in the solvent-equilibrated triplet state of 4-chloroanisole or

TABLE 16.3 Energetics for the Homolytic and Heterolytic Fragmentation of Some Aryl Halides

4-chloroaniline the halogen atom tilts out of plane. A further stretch of the bond encounters a moderate barrier and leads to a phenyl cation [79].

The occurring of a heterolytic path has been early suggested in a couple of cases [80], but has been recently more extensively investigated. It appears that this occurs efficiently from electron-donating substituted aryl halides in polar solvents. Also the parent cation has been obtained, though. In an inert matrix at 10 K, high energy irradiation cleaves iodobenzene and gives, among other species, the cation, which has been spectroscopically characterized. Doping the matrix with nitrogen or carbon monoxide produces the phenyldiazonium or benzoyl cation, respectively [81, Scheme 16.20].

Dehalogenation may lead to ring transformation. In particular, 2-chloro and 2-bromophenol eliminate HX and yield a ketocarbene that in turn undergoes a Wolff rearrangement [82, Scheme 16.21]. In the presence of oxygen, trapping of this intermediate gives a carbonyl oxide, detected by flash photolysis [83].

The formation of a small amount of 2-methyl-4,5,6,7-tetrachlorobenzoxazole from the irradiation of pentachlorophenol in acetonitrile has been rationalized through hydrogen chloride loss and solvent addition to the resulting ketocarbene [84, Scheme 16.21].

Apart from such mechanistic studies, the synthetic interest of heterolytic cleavage lies in the triplet state of the phenyl cation. The singlet cation (π^6n^0 localized structure) is completely unselective and reacts at diffusion controlled rate with any nucleophile. Its triplet counterpart is again a strong electrophile, but, as one may expect from its π^5n^1 electronic structure, more similar to a triplet carbene rather than to a localized carbocation [79,85]. This leads to a peculiar preference for reaction with π nucleophiles with respect to n nucleophiles (in fact, the rate of addition is higher by a factor $>10^3$) [86,87].

**SCHEME 16.20****SCHEME 16.21**

SCHEME 16.22

As mentioned earlier, aryl halides undergo efficient intersystem crossing. Thus, the cation is produced in the synthetically interesting triplet state. In practice, irradiation of the halides (fluorides and chlorides, although the mechanism applies to some bromides too) can be carried out in a polar (and thus usually nucleophilic) solvent, with no risk of competitive trapping of the phenyl cation. ISC to the singlet will occur at the adduct cation level and at this point addition of the nucleophilic solvent or other “typical cationic” reactions take place (Scheme 16.22).

The reaction has a synthetic interest since it allows the formation of an aryl–carbon bond starting from easily available halides. As mentioned, it occurs smoothly with electron-donating substituted fluorides and chlorides, and is thus complementary to both the $S_{RN}1$ process and to the thermal arylations involving transition metal catalysis, which both generally involve bromides and iodides and are favored by electron withdrawing substituents [88]. Attack to alkenes, alkynes, aromatics, and heterocycles is effective. The final product formed depends on the structure of the addend and on conditions. With alkenes, (β -substituted)-alkylbenzenes or allylbenzenes have been obtained. Mixtures can be formed because of the intervening of cationic rearrangements (Wagner–Meerwein type) in the alkyl moiety. The product distribution is simplified, and the synthetic value increased, when the reaction course is directed by the alkene substituents. As an example, phenyl alkenes give styrenes [89,90, see Scheme 16.23].

The biased reaction from the adduct cation may involve a fast cleavage when a good electrofugal group is present, such as a silyl group in the reaction with allyltrimethylsilane that gives an allylbenzene [91, Scheme 16.24] or in the reaction with silylenol ethers for the preparation of α -arylketones [92, Scheme 16.23].

The stabilization of the cationic site may help in directing and simplifying the reaction paths, for example, by making deprotonation from a tertiary carbon predominant over addition of a nucleophile

SCHEME 16.23

SCHEME 16.24

SCHEME 16.25

in the reaction with 2,3-dimethylbutene or by ensuring a sufficient permanence to the cation adduct, so that alcohol addition is effective in the reaction with 2,3-dihydrofuran [93, Scheme 16.25].

Still another possibility for a clean reaction is having the nucleophile in the addend itself. Thus, starting from alkenoic acids the initial attack by the phenyl cation onto the alkene moiety is followed by intramolecular attack by the carboxyl group [94, Scheme 16.26],

Alkynes undergo smooth arylation in a Sonogashira-like process [95, Scheme 16.27]

The arylation is effective with aromatics, giving biphenyls even when sterically hindered [96, Scheme 16.28] and with electron-rich heterocycles, where it occurs selectively on the most nucleophilic position free [97, Scheme 16.28].

When no π nucleophile is present (as a matter of fact one is necessarily present, viz. the aryl halide used as precursor; in fact a certain amount of “self-coupling” products are usually formed), the triplet cation is generally reduced via electron or hydrogen transfer by the solvent, since, as mentioned earlier, it does not add to nucleophiles. This can be considered as a mild method for the reductive dechlorination (and defluorination) in aromatic compounds [98, Scheme 16.29].

SCHEME 16.26

SCHEME 16.27

SCHEME 16.28

SCHEME 16.29

SCHEME 16.30

Charged nucleophiles add, however. Examples are the irradiation of electron-donating substituted aryl halides in the presence of iodide and cyanide, where a clean substitution results. In the latter case the procedure is a simple and cheap alternative to thermal methods for the preparation of benzonitriles [99, Scheme 16.30].

16.9 Application to Depollution

16.9.1 Direct Irradiation

Halogenated aromatics are important pollutants found in the gas phase, in water, and adsorbed on solid materials, and photochemical reactions may be an important decomposition path. A comparative study of various noncombustion methods has shown that, although it is impossible to establish an efficiency order because different test compounds give different answers, photochemistry certainly is a viable solution for the elimination of PCBs [100]. Studies in water (where a limit is the low solubility) indicate that the main process is solvolysis. Thus, chlorobenzene in deaerated water gives mainly phenol and chloride anion and a low amount of benzene and chlorobiphenyl [101]. Phenol is easily oxidized and thus the process may be thought to be directed toward mineralization.

Under different conditions, however, decomposition cannot always be equated to detoxification. In iced water, as an example, the main processes are reductive dehalogenation and coupling to di- and triphenyls, consistently with a homolytic cleavage and combination [102]. Dehalogenation occurs also in the irradiation of bromobenzene and some dihalo (Cl, Br) benzene in water ice. No phenols are formed, but rather coupling products, halobiphenyls. In these cases, photoproducts are formed that are more toxic and persistent than the starting pollutants.

In polychlorobiphenyls, photodechlorination has been examined as a potential method for the detoxification of marine sediment and found to be rather inefficient (much less, e.g., than radiolysis) [103]. However, the fact that in solution the process in the presence of amines is faster suggest that under optimized conditions this method may give satisfactory results. Indeed, with 2,3,4,5-tetrachlorobiphenyl it was found that a small amount of surfactant have been shown to lead to increased reductive dehalogenation and likewise humic acids at a low concentration to act as an additional hydrogen source, thus favoring degradation [104]. Conversely, liberation of chlorine or bromine from human-made materials, for example, compounds of industrial or agricultural use, may affect the destruction of the ozone layer in the stratosphere.

Dehalogenation, or at least dechlorination, becomes a minor path with higher aromatics, or with a part of them. Thus, photodegradation of chlorinated PAH (that appear to be present in graphite particles) involves processes different from cleavage of the aryl-Cl bond, primarily ring oxidation. The stabilization brought about by the insertion of a chloro atom may thus diminish the photoreactivity, and not increase it as the introduction of a new chemical path would be expected to do. The two effects are balanced, thus 9-chlorophenanthrene and 1-chloropyrene are more photolabile than the corresponding hydrocarbons and the reactivity increases when adding further chlorine atoms, whereas the contrary is true for 7-chlorobenz[a]anthracene and 6-chlorobenzo[a]pyrene with respect to the corresponding substituted hydrocarbons [105].

Among the many studies of the decomposition of halogenated materials in various environmental locations that have been studied, at least the case of decabromodiphenyl ether, a largely used flame retardant, should be quoted. This compound degrades in some weeks when adsorbed on kaolinite or montmorillonite, but in some months when adsorbed on a carbon-rich sediment. The reaction involves stepwise debromination [106].

Chlorobenzene may be a significant contaminant in gaseous effluents. It has been demonstrated that irradiation by low-pressure mercury lamps in a suitable photochemical reactor leads to the removal of this compound in the range 0.2–2 g/m³ starting concentration, with an increased efficiency in the presence of moisture [107]. An integrated UV-biofilter system has given excellent results [108].

16.9.2 Photocatalysis

Titanium photocatalysis, the technique par excellence in photodepollution, has obviously been applied to the degradation of aryl halides. Chlorobenzene and (polychloro)biphenyls have been investigated extensively [109], and 4-chlorophenol [110] has become the standard material for comparing the efficiency of variously prepared titanium sample [111], probably because the oxidation proceeds particularly smoothly (also in view of the adsorption of this polar compound onto the photocatalyst, essential in this heterogeneous technique). In the gas phase, it has been found that humidity decreases the rate of chlorobenzene degradation, because the layer of water prevents the adsorption of the pollutant (contrast with Section 16.8.1). The literature on this topic is quite extensive and ranges from the dependence on conditions [112], to the effect of added reagents, such as hydrogen peroxide [113] and to mechanistic issues [114].

Nanomaterials have proven effective for the reductive dehalogenation of aryl halides. As an example, nanocrystalline ZnS in the presence of triethylamine as sacrificial donor has proved to be effective with the sequential elimination of chlorine from di-, tri-, and tetrachlorobenzene. Nanocrystalline CdS is also quite effective: when using bulk photocatalyst, hexachlorobenzene is only partially reduced to pentachlorobenzene, but with the nanocrystalline material in the same time, a 1–4 mixture of 1,2,3,4-tetrachlorobenzene and 1,2,4,5-tetrachlorobenzene is formed. Defluorination likewise occurs under these conditions [115].

16.10 Conclusions and Outlook

The photochemistry of aryl halides seems to be destined to remain a favored field of investigation. Introducing a halogen on an aromatic ring is experimentally simple and produces a strong effect on the nature of the excited states. Thus, the photochemical and photophysical properties can be manipulated rather easily. It is expected that applications in diverse fields, from analytical methods to OLEDs will be further developed. Although some classes of photoreactions (e.g., cycloaddition) tend to give mixtures, the long established $S_{RN}1$ process and the more recent S_N1 arylations occur selectively under mild conditions. These appear to be useful preparative methods that deserve to be ranged among the general synthetic procedures. Furthermore, aryl halides have convenient properties also in the ground state, which makes them largely used in industry and agriculture and thus, unfortunately, common among pollutants. There again photochemistry has an important role for their degradation in the environment.

Acknowledgment

Miss Carlotta Raviola is thanked for her help in the literature search.

17.1 Introduction

Phosphate and especially sulfonate esters (e.g., triflates, mesylates, and tosylates) are extensively used in organic chemistry, mainly under thermal conditions, with the R groups (in compounds **1** and **2** in Schemes 17.1 and 17.2) being the most important moiety. The phosphate or sulfonate esters act as suitable leaving groups having the exclusive role of activating the R groups for the synthesis of the target compound (R–Nu) and are thus eliminated at the end of the reaction (paths a and b). Actually, the capability of sulfonate esters as leaving groups in aliphatic nucleophilic substitution rivals that of the widely used halogen anions. Moreover, an alcoholic function can also act as a leaving group when transformed into a sulfonate ester and, in the last years, vinyl or aryl sulfonates have attracted increasing attention as the electrophilic partner in metal-catalyzed reactions (Scheme 17.2, path b). By means of this approach, Ar–X bonds (X = C, N) have been easily formed by metal-catalyzed activation of the Ar–O bond [1]. However, this is not the same for phosphate esters, which are virtually unused in the synthesis except when activated by a benzyl or a vinyl group and again under metal catalysis (Scheme 17.1, path a) [2].

Contrary to thermal reactions, the photochemical approach involves the activation of these esters by the use of light. More precisely, in phosphate derivatives (e.g., **1**) the irradiation can cause the cleavage of a C–O bond (R–O in Scheme 17.1), whereas in sulfonate esters (e.g., **2**) either a C–O (cleavage c) or a S–O bond (cleavage d) can be broken (Scheme 17.2).

In most photochemical processes, however, the R group has the role of protecting the particularly significant ester moiety that is liberated upon exposure to light. Accordingly, the R group is eliminated (as a rearranged or functionalized R'' group), thus acting as a photoremovable ester-protecting group [3a]. The photochemical reactions of phosphate esters are devoted to release stable molecules mainly of biological interest via photocleavage of a C–O bond in a starting precursor (known as caged compound;

SCHEME 17.1

SCHEME 17.2

Scheme 17.1, path a') [3b]. Alternatively, the sulfonate can be liberated as a free strong sulfonic acid via the photoinduced cleavage of the O-S bond (Scheme 17.2, path b') in the case of aromatic ester precursors (2, $R = Ar$). These derivatives are commonly called photoacid generators (PAGs) and have found application in photolithography [4] or in biology. The sulfonyl radical formed in the latter process, however, can alternatively react with the other radical species generated from the initial cleavage, leading to photo-Fries rearranged products (Scheme 17.2, path b''). The use of phosphate and sulfonate esters for the synthesis of lead compounds via cleavage of the C-O bond, however, has recently emerged (Scheme 17.1, path a'', Scheme 17.2 path b''), which mainly involves the $S_{RN}1$ reaction of vinyl or aryl phosphates [5] or the S_N1 reaction of aryl phosphates and sulfonates [6]. In rare instances, the cleavage of the $R'-S$ bond has been reported as in the photochemistry of alkyl benzenesulfonates (see Section 3.1).

In conclusion, the aim of this chapter is to review the main paths involved in the photochemistry of phosphate and sulfonate esters, focusing on their application in organic synthesis or in other fields of industrial interest.

17.2 Photochemistry of Phosphate Esters

As stated earlier, the main role of phosphate esters in photochemistry is related to their application as protecting groups. Representative examples dealing exclusively with phosphate ester derivatives, where the C–O bond is cleaved upon direct or sensitized excitation, are discussed here. In the first part, the main classes of photoprotecting groups that liberate the (substituted) phosphates upon UV light irradiation are listed. Many phosphates have a biological functionality (e.g., ATP), that can be released in solution starting from biologically inactive phosphates referred to as “caged molecules” (e.g., caged ATP). These compounds are of fundamental importance in biochemistry, since the delivery of active molecules to living cells is feasible having recourse to an exposure to light. Scheme 17.3 illustrates the main phosphate protecting groups, including the (nitro)benzyl phosphate esters (a), the benzoin esters (b), the (*p*-substituted)phenacyl (c), and methylcoumaryl phosphates (d).

17.2.1 (Nitro)benzyl Phosphates

o-Nitrobenzyl compounds are the most widely known protecting groups for the phosphate function [2,7,8]. The mild deprotection step (no harsh chemical treatment is needed for removal) is well suited with biological conditions and has no remarkable effects on intracellular processes. Accordingly, the *o*-nitrobenzyl compounds are in many cases photoactivable derivatives of biologically significant molecules. Although the photochemistry of these compounds is well known, no exhaustive information about the reaction mechanism is available so far. The first step is thought to be the light-induced tautomerization of the *o*-nitrobenzyl phosphate moiety (as in 3, Scheme 17.4) to the quinonoid *aci*-nitro tautomer (4). As a result, the phosphate and the corresponding nitroso aromatic are formed, probably via the intermediacy of a hemiacetal (5).

Some drawbacks in the use of these derivatives have to be stressed, however, including the slow release of the active species, as well as the highly absorbing and reactive side products (e.g., the nitrosoaromatic) formed. Nevertheless, some caged compounds based on *o*-nitrobenzyl esters are commercially supplied as molecular probes [9].

Selected recent new applications are presented here. The first deals with the caged D-erythro-sphingosine 1-phosphate (6), which was introduced in cultured cells. UV illumination of this molecule led

SCHEME 17.3

SCHEME 17.4

SCHEME 17.5

to the liberation of D-erythro-sphingosine 1-phosphate (7) along with two molecules of *o*-nitrosoacetophenone (Scheme 17.5) [10]. This was considered an elegant way to stimulate the DNA synthesis by the enhancement of the intracellular level of 7.

The release of oligonucleotides from the corresponding caged derivatives is of obvious importance and not trivial since these molecules have to penetrate the lipid membranes of the eukaryotic cells. These derivatives may find application in designing new types of antisense oligonucleotides or investigating the nucleic acid interactions with proteins and other compounds. As an example, the *o*-nitroveratryl moiety was linked to thymidine dinucleotides and thus used as a photolabile protecting group. The presence of two methoxy groups in the aromatic ring markedly increased the absorbance at longer wavelength and 365 nm irradiation was adopted in this case [11].

The phosphate esters of adenine nucleotide analogues (e.g., caged ATP) are likewise widely studied compounds [12] both from the mechanistic point of view [13] and as a means to detect molecular interactions in biological systems. As an example, the interaction between ATP photoreleased from its inactive P³-[1-(*o*-nitrophenyl)]ethyl ester and bovine intestinal alkaline phosphatase has been studied by reaction-induced infrared difference spectroscopy [14]. This allowed the study of the molecular interactions between the nucleotide and the enzyme in the same cuvette with no interference by the other biological compounds present. Phosphate-related compounds, viz., the phenylphosphonamidate (8, Scheme 17.6), can likewise act as precursors of biological compounds [15].

In this case, an *o*-nitrobenzyl photolabile moiety functioned as a linker between a spermine molecule and a solid phase consisting of polyethylene oxide beads. The polyamine used allowed capture of DNA by formation of a complex via strong electrostatic interactions. Such a complex was then completely released using light (365 nm) under very mild conditions (no need for high temperature or acidic/basic

SCHEME 17.6

conditions) [15]. The spermine derivative **10** was completely soluble in the reaction medium contrary to the insoluble supported nitrosoaromatic by-product **9**. The thus obtained controlled release of nucleic acid is of marked importance in several gene transfer applications.

Very recently, a quantitative liberation of inorganic phosphate from α -carboxy-4-nitrobenzyl phosphate caused by an initial photorelease of carbon dioxide has been reported [16].

Benzyl phosphates lacking the *o*-nitro group (as **11**, Scheme 17.7) were found to be likewise smoothly photocleaved, forming various benzyl cation-derived products depending on the reaction medium along with negligible amounts of the corresponding bibenzyls (Scheme 17.7) [7,17–19]. The reaction mechanism changes dramatically from the *o*-nitro analogues since a heterolytic cleavage of the C–OP bond from the ester singlet state is envisaged [7,17–19]. Thus, benzyl ethers **14** and amides **13** (formed from a Ritter reaction between a benzylic cation and MeCN) were obtained in a good yield by using methanol (or butanol) and aqueous acetonitrile, respectively, as the reaction media. Noteworthy, the reaction can lead to C–C bond formation as in the case of the synthesis of benzylated derivative **12** by irradiation of **11** in benzene. Moreover, among the cases examined, the most efficient and clean photofragmentations were those of naphthylmethyl phosphates.

A new class of photolabile *N*-alkyl-4-picolinium phosphate esters has been recently introduced by Falvey and coworkers [20]. The reaction was sensitized by suitable pyrromethene or coumarin-based laser dyes via a photoinduced electron transfer (PET) process. Tungsten lamp ($\lambda > 400$ nm, 300 W) irradiation of an acetonitrile solution of phosphate **15**, the sensitizer, and the radical scavenger 1,4-cyclohexadiene caused the reduction of **15** to radical **16**. Quantitative phosphate release then took place with the concomitant formation of the picoline salt **17**, as illustrated in Scheme 17.8 [20].

Ar = Phenyl, 1- or 2-naphthyl

SCHEME 17.7

SCHEME 17.8

17.2.2 Benzoin Phosphates

The product distribution obtained in the photolysis of benzoin phosphates depends on the solvent used. Accordingly, irradiation of benzoin ester **18** in MeCN led to the diradical intermediate **19** by a cyclization step; formation of benzofuran **20** besides diethyl phosphoric acid release ensued [17]. On the contrary, in protic media such as aqueous acetonitrile or fluorinated alcohols, a different path was followed where a heterolytic cleavage of the C–O bond took place liberating a phosphate anion with the concomitant formation of triplet cation **21** (Scheme 17.9) [21]. ISC and solvent addition (water in this case) completed the sequence. Interestingly, formation of benzoin **22** or related products was a very minor side reaction in acetonitrile. The mechanism has been recently confirmed by a combined femto-second transient absorption and nanosecond time-resolved resonance Raman study [22]. This photoreaction thus provides an entry to α -keto carbocations (e.g., **21**), an intermediate so far unexploited in organic chemistry.

SCHEME 17.9

SCHEME 17.10

The type and the position of substituents on the phenyl rings markedly affect the quantum yield of phosphate release. In fact the presence of two methoxy groups in position 3' and 5', or 2' and 3' induced a fast photocleavage, whereas when in position 2' and 5' made the benzoin photostable [23].

Benzoin phosphate esters were exploited as phototriggers for the photorelease of biologically active molecules, such as cAMP as illustrated in Scheme 17.10, where irradiation of desyl "caged" cAMP (**23**) in an aqueous dioxane mixture liberated cAMP, along with phenylbenzofuran, which is biochemically benign [24].

17.2.3 Phenacyl Phosphates

Phenacyl derivatives (e.g., **24**) were later introduced to improve the performance of benzoin derivatives by removing the phenyl moiety from the α position and thus eliminating the stereogenic center present (Scheme 17.11) [25]. The mechanism of phosphate release strongly depends on the substituents present on the aromatic ring (usually in *para*-position with respect to the carbonyl group). With unsubstituted

SCHEME 17.11

SCHEME 17.12

phenacyl phosphates the liberation of phosphate anion can be induced by a PET process sensitized by 9,10-dimethylantracene (DMA) as the reductant (Scheme 17.11, path a) [26]. The resulting radical anion $24^{\bullet-}$ cleaved, forming the phosphate anion and a phenacyl radical.

An interesting result was found in the photoreactions ($\lambda = 300\text{ nm}$) in a Tris buffer (pH = 7.2) of phenacyl phosphates having electron-donating groups. In fact, an amino group strongly decreased the photoreactivity of the ester, whereas the reaction quantum yield of acetamido and carbamoyl derivatives was quite high ($\Phi = 0.34\text{--}0.38$, Scheme 17.11, part b) [27]. Unfortunately the reaction was not clean since several phenacyl deriving by-products were formed along with acetophenone and phosphate anion (Scheme 17.11, part b). A more clear-cut reaction took place when substituting a methoxy group for the carbamoyl group, since only two products (acetophenone and a rearranged product, namely *p*-methoxyphenylacetic acid) were detected [28].

Moreover, when the phosphate was substituted with a *p*-hydroxyphenacyl group, the aqueous solubility was dramatically enhanced and, apart from the phosphate group, *p*-hydroxyphenylacetic acid was the exclusive photoproduct (Scheme 17.11a). Several investigations have been carried out with the attempt of clarifying the mechanism of this photo-Favorskii process [29]. The reaction sequence is initiated by 324 and the phosphate release is concomitant with a water-assisted deprotonation to give the triplet biradical **25**. The spirodienedione intermediate **26** is then formed and hydrolyzed to the phenylacetic acid in aqueous medium [29b]. Apart from the mechanistic importance, the *p*-hydroxyphenacyl group was useful for the liberation of biochemical probes. As an example, ATP was photoreleased from *p*-hydroxyphenacyl-caged ATP (**27**) with a quantum efficiency of 0.30 via the triplet state (Scheme 17.12) [27].

17.2.4 Coumarylmethyl Phosphates

Coumaryl derivatives have been recently introduced as innovative photolabile precursors [17,30], since their UV absorption spectrum has an enhanced redshift with respect to both phenacyl esters and benzoin derivatives. Moreover, coumarylmethyl esters are among the fastest-reacting caged compounds.

SCHEME 17.13

The cleavage takes place as described in Scheme 17.13, where phosphate **28** is initially excited to the singlet state (${}^1\mathbf{28}$), causing a marked weakening of the C–O ester bond that causes a solvent-assisted photoheterolysis to a singlet ion pair ${}^1[\mathbf{29^+} + \mathbf{30^-}]$. Water trapping by $\mathbf{29^+}$ forms (coumarin-4-yl)methyl alcohol **31** and liberates an equivalent of phosphoric acid [**31**].

As for the above, various caged compounds containing the coumarylmethyl moiety have been synthesized. As an example, caged cytidine 5'-diphosphate **32** that contains the photolabile (7-diethylaminocoumarin-4-yl)methyl moiety was prepared (Scheme 17.14) [32]. The release of cytidine 5'-diphosphate (**33**) was used to study the *Escherichia coli* ribonucleotide reductase (RNR) and took place smoothly upon irradiation at wavelengths between 365 and 436 nm (where the RNR is actually transparent). The quantum yield of disappearance of **32** and the rate constant of the formation of **33** have been measured and found to be 0.029 and $2 \times 10^8 \text{ s}^{-1}$, respectively [32].

Tailor-made coumarin derivatives have been obtained by varying the substituents on the aromatic ring. As an example, the presence of a bromo substituent in a hydroxycoumarin has the effect of accelerating the ISC of the molecule and at the same time amplifies the acidity of the phenolic OH group [33]. The negative charge of the phenolate group thus imparted a better hydrophilicity to the system increasing its water solubility. Caged cyclic nucleotides with an extinction coefficient $>14,000$ in the 375 nm region have been devised accordingly [33].

As noted earlier, the phosphate moiety is liberated as a free acid. Since the diethyl phosphate monoacid has a $\text{p}K_{\text{a}}$ value of 0.71 [34], coumarylmethyl esters can be viewed as “caged protons,” suitable to induce a rapid pH jump in solution when photocleaved. This phenomenon can also have a biological effect, as protons have an active role in cellular signal transduction. Since nitrobenzyl derivatives can have a distinct disadvantage of forming reactive *o*-nitrosocarbonyl by-products, (6,7-dimethoxycoumarin-4-yl)methyl (DMCM) diethyl phosphate as well as [7-(dimethylamino)coumarin-4-yl]methyl (DMACM) diethyl phosphate have recently been tested as valid alternatives [34]. As for the DMACM phosphate, it showed a high extinction coefficient ($\epsilon = 16,100$ at 386 nm), a release quantum yield of 0.36 and it was used for the study of proton migration along the membrane surface.

SCHEME 17.14

17.2.5 Aryl Phosphates

Aryl phosphate esters (contrary to the corresponding sulfonates) are not actually used for arylation reactions via the commonly used metal-mediated coupling methodologies [1]. On the contrary, the Ar-OP bond is more labile when irradiated with UV light and this process could have interesting and yet unexploited applications in organic synthesis. The photochemistry of aryl phosphates has been known for 50 years, when Havinga et al. discovered that the photohydrolysis of *m*-nitrodiethylphosphorylbenzene was accelerated by light [35] and this reaction actually opened the path to photonucleophilic aromatic substitutions [36,37]. Depending on the reaction conditions, the predominant cleavage of the P-O (in neat water, Scheme 17.15, path a) or the C-O bond (in alkaline aqueous medium, path b) has been reported [37,38]. *m*-Nitro substituted phosphates were the most reactive isomers among the substrates considered and this laid the basis of a milestone in the photochemistry of aromatics, viz., the so-called “*meta*-effect.” Despite the importance of such a discovery, however, only a handful of photosubstitution reactions involving aryl phosphates are known [36].

Contrary to Havinga's experiments on aryl phosphates substituted with an electron-withdrawing group, electron-rich aryl phosphates displayed a different intriguing chemistry. Thus, irradiation in polar solvents (e.g., 2,2,2-trifluoroethanol (TFE) or aqueous acetonitrile) of *N,N*-dimethylamino (e.g., **34a**) or

SCHEME 17.15

SCHEME 17.16

methoxy-substituted (e.g., **34b**) aryl diethyl phosphates induced heterolysis of the aryl–oxygen bond forming the corresponding aryl cations (**35a⁺** and **35b⁺**, Scheme 17.16) [39]. The importance of this process resides in the fact that the formation of the last species is a rare occurrence thermally, requiring the solvolysis of precursors with limited availability, such as substituted phenyl triflates or (trifluoromethanesulfonyl)oxydienynes [40]. Apart from these disadvantages, under these conditions a rather unselective strong electrophile such as a singlet phenyl cation is formed. Contrary to thermal reactions, the photochemical generation of aryl cations allows their formation in the triplet state, a rather reactive but selective strong electrophile [41]. Accordingly, a new strategy based on ArS_N1 reactions is thus emerging and involves the chemoselective addition of triplet phenyl cations onto suitable carbon nucleophiles to give Ar–C bonds under mild conditions [6,42,43]. Noteworthy, no concurrent cleavage of the O–P bond takes place.

Schemes 17.17 and 17.18 illustrate some examples regarding the reaction of selected nucleophiles with the 4-*N,N*-dimethylaminophenyl and 4-methoxyphenyl triplet cations, respectively.

Cation **35a⁺** smoothly reacted with cyanide ion in MeCN/H₂O 3:1 forming 4-*N,N*-dimethylaminobenzonitrile in 70% yield (Scheme 17.17, path a) [44]. Noteworthy, the large amount of water present in the solvent mixture did not interfere with the reaction (no phenols were formed), but actually favored both the photoheterolytic step and the dissolution of the cyanide salt (KCN). This straightforward synthesis of benzonitriles was thus possible by substituting light for the metal catalyst required for activating the Ar–O bond. Terminal alkenoic acids (e.g., 5-pentenoic acid) were suitable for the construction of oxygen containing five-membered rings, an important structural motif present in many

SCHEME 17.17

SCHEME 17.18

biologically active natural compounds (path b) [45]. Thus, the electrophilic addition of the phenyl cation onto alkenoic acids occurred efficiently and was followed by an intramolecular attack by the carboxylic group, resulting in the formation of a benzyl substituted γ -lactone (path b) [45]. This one-step procedure mimics the well-known iodo-lactonization reaction and has little precedent under Pd-catalyzed conditions. Electrophilic aromatic substitution-like reactions were also feasible. Accordingly, both benzene [39] or methyl-substituted aromatics (e.g., xylene) [46] could be arylated affording the biaryl derivatives via an Ar–Ar bond formation in 96% and 52% yield, respectively (path c).

Scheme 17.18 illustrates the versatile chemistry of 4-methoxyphenyl cation ($35b^+$). Allyltrimethylsilane is one of the most studied nucleophiles, since allyl aromatics can be formed in one step by this route. In this case, TFE must be used as the solvent along with triethylamine as the base. Acetone sensitization (0.9 M) was also needed to increase the reaction efficiency (path d) [39]. A metal-free protocol for the mild alkynylation of aromatic compounds again involves the reaction of cation $35b^+$ with terminal alkynes. When 1-hexyne was used, aryl alkyne **36** was formed in 90% yield in TFE (path e). In this case, trapping of $35b^+$ by an alkyne resulted in the generation of a vinylenebenzenium ion, which gave **36** after a complete chemoselective deprotonation step [47]. A photochemical multicomponent reaction is a rare occurrence, but irradiation of **34b** in a methanolic solution of ethyl vinyl ether afforded acetal **37** in 45% yield via a three-component reaction (path f) [48].

As evidenced in Schemes 17.17 and 17.18, the arylation was particularly effective when the phosphate group was placed in the *para*-position with respect to the activating group (whether NMe_2 or OMe). Nevertheless, the isomeric *ortho*- and *meta*-methoxyphenyl phosphates likewise underwent the photoheterolysis of the Ar–O bond [49]. In the latter case, however, the triplet phenyl cation formed easily underwent an ISC process to the more stable singlet cation and the subsequent solvolysis reaction became more competitive [41,49].

Scheme 17.19 illustrates this quite interesting new “*meta*-effect” in photochemistry, which, contrary to Havinga’s reaction, does not involve the multiplicity of the excited state but that of the intermediate formed upon photolysis [49]. Thus, irradiation of phosphate **38** in TFE in the presence of benzene led to the expected arylation product **39** in 34% yield. The high stabilization of the triplet cation formed, however, allowed ISC to give the singlet cation that gave the trifluoroethylether **40** in 25% yield by solvent addition.

A different approach for the phosphate group release in aryl phosphates relies on the $\text{S}_{\text{RN}}1$ reaction. This is a well-known process that mainly allows the formation of new C–C bonds by photostimulation

SCHEME 17.19

of a mixture containing an aryl-X (or vinyl-X) derivative (mostly $\text{X} = \text{I}, \text{Br}$) in the presence of a strong nucleophile (mainly an enolate anion) [5,43]. The phosphate ester can act as the leaving group of the reaction, though this is seldom used [5]. Most of the reported examples deal with the use of tin anions (Me_3SnNa or Ph_3SnNa) as electron donors for the formation of new interesting C–Sn bonds. Accordingly, various arylstannanes were accessible starting from aryl diethyl phosphate esters [50–54]. Methoxy group substituents present in the aryl esters were tolerated easily in the reaction, whereas if a halogen ($\text{I}, \text{Br}, \text{Cl}$) was also present, this resulted in substitution along with the phosphate ester group [51].

As an example, Scheme 17.20 illustrates the synthesis of 2,7-bis(trimethylstannyl)naphthalene (**43**) from the corresponding alcohol **41**. 2,7-Dihydroxynaphthalene (**41**) was first transformed in the

SCHEME 17.20

SCHEME 17.21

SCHEME 17.22

diester **42**, which underwent an ArS_{RN}1 process. Stannane **43** was then isolated by two consecutive substitutions of the phosphate ester by a tin nucleophile [54].

If the phosphate ester is substituted with more than one aryl group, a different photochemistry results [55,56]. Biaryl or triarylphosphates may seem unusual starting materials for the synthesis of biphenyls. Nevertheless, the photolysis of triaryl esters in alcoholic solvent formed a biaryl derivative with the concomitant elimination of a monoaryl phosphate [55]. The reaction, one of the rare examples of metal-free formation of an Ar–Ar bond, was satisfactory and clean only when at least two aryls bore a methoxy group as depicted in Scheme 17.21.

Moreover, the amount of biphenyl formed could be increased by adding water to the reaction mixture [55c]. Alkylbiaryl phosphates can be likewise employed [55b]; the formation of biphenyls is similar to that reported for triarylphosphates and involves an intramolecular excimer, generated from the singlet state of the starting ester. On the contrary, a cationic migration of the aryl group to a neighboring olefinic moiety was postulated when irradiating alken-1-yl aryl methyl phosphates, where a mixture of arylalkanones and aryl alkenyls was usually formed [56].

17.2.6 Vinyl Phosphates

In rare instances the S_{RN}1 reaction can also be applied to vinyl phosphate esters (e.g., vinyl diethyl phosphates) obtained from the corresponding ketones under thermodynamic- or kinetic-controlled enolization. New tin–carbon bonds were formed under photostimulation of a liquid ammonia solution of triorganostannyl anions (e.g., sodium trimethylstannide) and the vinyl phosphate. The reaction is of significant interest, since vinyl stannanes are useful intermediates in metal-catalyzed reactions. Unfortunately, this regioselective substitution reaction seemed to apply only to conjugated vinyl phosphates such as **44** (Scheme 17.22) [57] or (diethoxyphosphoryl)oxy-1,3-cyclohexadienes [58].

17.3 Photochemistry of Sulfonate Esters

As mentioned in Section 17.1, sulfonate esters can be both used as photoremovable protecting groups (e.g., of a hydroxy group) and as PAGs, where a sulfonic acid is liberated in the process. The photochemistry of these esters varies according to the type of sulfonates investigated. It is only recently that aryl esters have been employed in organic synthesis for metal-free formation of Ar–C bonds. The photolysis of alkyl (mainly benzyl) or phenyl sulfonate esters [43] will be briefly described here.

17.3.1 Aliphatic Sulfonates

Alkyl arenesulfonates of general formula $\text{Ar-SO}_2\text{-OAlkyl}$ can undergo a photochemical cleavage either of the Ar-S or the S-OAlkyl bond depending on the reaction conditions, as summarized in Scheme 17.23.

Izawa and Kuromiya reported that, in the irradiation of methyl benzenesulfonate in methanol ($\text{Ar} = \text{Ph}$, $\text{Alk} = \text{Me}$ in Scheme 17.23), three products were detected, viz., benzene (34%), biphenyl (10%), and anisole (traces) with a $\Phi = 0.07$ [59]. The authors postulated a scission of the Ar-S bond (Scheme 17.23, path a) from the excited singlet state of the starting sulfonate. The formation of the Ar accounted for the formation of benzene (via hydrogen abstraction) and biphenyl (via radical coupling). The small amount of anisole arose from the radical coupling between an alkoxy and an aryl radical via the $a \rightarrow a' \rightarrow a'''$ sequence. Homolytic fragmentation of the S-OAlk bond was excluded (Scheme 17.23, path b) since no aryl radical could be formed in such a case because the sulfur dioxide loss from ArSO_2^\bullet was estimated to be largely endothermic and, moreover, no sulfonic anhydride derivatives, such as $\text{ArSO}_2\text{-SO}_2\text{Ar}$, were detected.

A similar behavior was reported in the photolysis of several alkyl arenesulfonates in different solvents where the corresponding aliphatic alcohols (Alk-OH) were isolated in good yields [60]. Accordingly, the cleavage of the Ar-S bond was followed by SO_2 elimination from Alk-OSO_2^\bullet (path a') ensued by hydrogen abstraction from the reaction medium (path a''). The presence of a base caused a more efficient and cleaner reaction [60]. On the other hand, in benzene, biphenyls arising from aryl radical addition onto the solvent were also detected.

The leaving group capability of sulfonate esters under photolytic conditions has been employed in the photodeprotection of the alcoholic groups (protected as tosylate esters) in carbohydrates. A dated example deals with the photodeprotection at room temperature of the tosyl group of methyl 6-O-tosyl- α -D-glucopyranoside in a methanolic solution of a base, such as sodium methoxide. After 5 h irradiation the parent methyl- α -D-glucopyranoside was recovered in 90% yield [61]. Further studies demonstrated that the first step of the reaction involves an electron transfer process between the sulfonate ester and the base forming the radical anion of the ester (Scheme 17.23, path c); the following cleavage of the S-OAlk bond liberates the alkoxyde anion, which, upon protonation, releases the desired sugar (paths d and e). As expected, the process was accentuated by increasing the electron-donating property of the base. Aliphatic amines such as DABCO, Et_3N , and $i\text{-Pr}_2\text{NEt}_2$ could be used since the ΔG_{et} between the singlet excited state of the protected sugar and the amine was apparently exoergonic (by ca. 23 kcal/mol) [62]. The mechanism was confirmed by laser flash photolysis studies, which detected both the DABCO

SCHEME 17.23

SCHEME 17.24

radical cation and the *p*-tolylsulfonyl radical [62]. Hydroxide anion can also be used as the base, however, as seen in the quantitative detosylation of 1,2:3,4-di-*O*-isopropylidene-6-*O*-(*p*-tolylsulfonyl)- α -D-galactopyranose when irradiated in methanol in the presence of excess NaOH (2.5 equiv.) [62]. An elegant application of this photodeprotection procedure was reported in the synthesis of mithramycin analogues starting from compound **45**, which has three orthogonal OH protecting groups (Scheme 17.24) [63]. The tosyl group was selectively removed to afford **46**, by irradiation of a methanolic solution of **45** (triethylamine as the electron donor) eliminating the need for acidic or basic conditions, which could have removed the other OH protecting groups. Prolonged irradiation, however, caused a partial loss of the benzyl group (Bn) [63].

In some cases, the liberation of the sulfonic group takes place as the secondary step of a photoreaction, as in the benzoin derivative **47** (Scheme 17.25) [64]. In this case, the reaction was initiated by a C–C homolysis of the **47** triplet state, yielding a benzoyl and an α -hydroxy- α -sulfonyloxymethylbenzyl radical. The latter radical rearranged to the phenacyl radical **48** with the concomitant liberation of methanesulfonic acid. Heterolytic cleavages were ruled out by the positive radical-trapping experiments. Actually, sulfonate **47** acted as a photoacid radical generator (PARG), which was able to initiate both a radical polymerization and a polycondensation simultaneously. As an example, derivatives such as **47** were useful as initiators in photocuring processes [65].

17.3.1.1 (Nitro)benzyl Sulfonates

Both *ortho*- and *para*-nitrobenzyl sulfonates (or sulfates) have been largely applied as PAGs [66–68] in chemically amplified deep UV (248 nm) photoresists [4,69,70]. Contrary to other PAGs (e.g., triphenylsulfonium salts), these derivatives have the advantage of being less polar and, accordingly, do not tend to phase separate when present in polymer matrices [69]. Unfortunately, the quantum yields of decomposition of these esters were not high enough, in fact never exceeding 0.16 [69]. The mechanism of acid release in nitrobenzyl sulfonates depends on the position of the nitro group on the aromatic ring (*ortho*- or *para*-). In the former case, the mechanism is common for other *o*-nitrobenzyl derivatives and involves

SCHEME 17.25

a photoenolization step followed by formation of the *o*-nitrosoaromatic derivative and liberation of the sulfonic acid (see Scheme 17.4, X = R-SO₃) [70].

These PAGs were also used in rapid biomedical release applications [71] or to study the effect of a fast pH decrease on protein conformational changes, as well as to investigate protein folding driven by protonation of carboxylate side chains. Unfortunately, in the previous case the *o*-nitrosobenzaldehyde formed during the process could be oxidized under the photolytic conditions and the carboxylic acid thus formed could interfere with the FTIR measurement used to follow this phenomenon. Since the changes to the resulting IR absorbance of the PAG should be as minimal as possible after irradiation, a sulfate (e.g., the 1-(*o*-nitrophenyl)ethyl sulfate, $\Phi = 0.47$) was therefore employed as a new caged proton [72]. The large pH jump obtained with this system was able to induce a partial unfolding of metmyoglobin [72].

Unlike *o*-nitrobenzyl esters, the corresponding *p*-nitro derivatives do not dissociate upon photolysis since they do not contain a benzylic carbon-hydrogen bond *ortho*- to the nitro group. Nevertheless, photoinduced monoelectronic reduction of *p*-nitrobenzyl esters causes the release of the sulfonate group from the intermediate radical anion. The process can take place inter- or intramolecularly as depicted in Scheme 17.26. In the first case (Scheme 17.26, part a), compound **49** functioned as a photoactivable surfactant since a hexadecyl sulfonate group was photoreleased by means of a PET reaction with 2-ethyl-9,10-dimethoxyanthracene (**50**) [73]. The process was investigated for the photoinduced interfacial adhesive forces modification induced by the surfactant in photosensitive imaging systems [73].

SCHEME 17.26

Intramolecular electron transfer processes, however, can be induced by tethering an appropriate donor moiety to the *p*-nitrobenzyl sulfonate group [74]. As a result, a C–O cleavage takes place (from **52**, see Scheme 17.26, part b) if it is competitive with the deactivation of the lowest singlet excited state of the aromatic sulfonyl moiety in **51**. Apart from the rate of the intramolecular electron transfer process, the factors that affect the photocleavage rate are the feasibility of C–O bond scission and the stability of the benzyl-type radical formed **54**[•] [74a,b]. The first donor investigated was 9,10-dimethoxyanthracene in *p*-nitrobenzyl 9,10-dimethoxyanthracene-2-sulfonate [74a,b]. The photocleavage led to radical **54**[•] (that in turn dimerized) and to the sulfonate radical **53**[•]. The latter radical either formed the corresponding sulfonic acid or lost sulfur trioxide, thus generating a phenyl radical that, in the event, coupled with **54**[•] to give the diarylmethane **55**.

In the effort to design more efficient PAGs, *p*-nitrobenzyl sulfonate esters linked to donors having a lower oxidation potential than 9,10-dimethoxyanthracene were next tested [74c]. Accordingly, it was found that upon irradiation, *p*-nitrobenzyl 5-dimethylaminonaphthalene-1-sulfonate and *p*-nitrobenzyl pyrene-1-sulfonate dissociated more efficiently ($\Phi = 0.16$ – 0.20) with respect to the previous anthracene-based sulfonate studied.

Benzoin 4-substituted benzenesulfonates were likewise used as PARs. Thus, the crosslinking of a film of 3-acryloxypropyl trimethoxysilane containing 1% of the sulfonate smoothly took place upon UV irradiation. The photocuring process induced a concomitant polymerization of the acrylate units and a polycondensation of the trimethoxysilane groups, as demonstrated by FT-IR and Raman spectroscopy analyses [75].

In Section 2.4 the photoreactivity of coumarylmethyl phosphate derivatives was described. Similar (coumarin-4-yl)methyl sulfonates (and sulfates) have been devised for the photogeneration of a strong acid in solution (e.g., methanesulfonic acid). The cleavage also occurred by photosolvolysis of the $\text{RCH}_2\text{--OSO}_2\text{X}$ bond (see again Section 2.4) [76]. Sulfonates have been demonstrated to be better leaving groups than phosphates and this was rationalized mainly by the different $\text{p}K_{\text{a}}$ values of the acids released. The $\text{p}K_{\text{a}}$ value for methanesulfonic acid (-1.54) is lower than that of diethyl phosphoric acid (0.71) and the sulfonate derivatives exhibit a higher photoreactivity, accordingly. As a result, the quantum yield of release of (7-methoxycoumarin-4-yl)methyl sulfonate ($\Phi = 0.08$) was measured and found to be roughly twice as much of the corresponding diethyl phosphate ($\Phi = 0.037$) [76]. Substituting a *N,N*-dimethylamino group for a methoxy group in the coumarin ring gave a highly photosensitive compound with both a high extinction coefficient ($17,100$ at 388 nm) and a high photoacid generation quantum yield (0.79) [34].

17.3.2 Aryl Sulfonates

Aryl sulfonates, whether $\text{Ar}'\text{--SO}_2\text{--O--Ar}$ or $\text{Alkyl--SO}_2\text{--O--Ar}$, generally lose the sulfonyl group when exposed to UV light with a mechanism that may change according to the ester structure. Thus, aryl sulfonates (similarly to aryl phosphates, Section 2.5) can be interesting triplet phenyl cation precursors, provided that the aromatic ring bears an electron-rich substituent (again a OMe or a NMe_2 group) [39]. The efficiency of formation of these cations depends mainly on the sulfonate used, since the photo-Fries process can compete in some cases (see the following). As an example, aryl tosylates were found unsuitable for the phenyl cation chemistry since no arylation occurred starting from 4-dimethylaminophenyl tosylate and low arylation yields were obtained from 4-methoxyphenyl tosylate [39]. On the contrary, aryl-substituted mesylates and triflates were successfully used, as shown in Schemes 17.27 and 17.28. 4-Methoxyphenyl mesylates and triflates gave the corresponding 4-methoxyphenyl cation that was used in some arylation reactions, such as those forming estragole **56** (quantitative yield, Scheme 17.27, path a) [39], aryl alkynes (**57** and **58**, path b) [47], and a benzyl lactone (**59**, path c) [45].

4-Dimethylaminophenyl cation was only photochemically generated with the use of mesylate **60**, since the corresponding triflate led almost exclusively to the photodeprotection of the triflate group [39]. Typical arylation reactions are shown in Scheme 17.28 and involve the synthesis of

SCHEME 17.27

SCHEME 17.28

4-*N,N*-dimethylaminobenzonitrile (**61**, 56% yield, path d) [44], β -aryl acetal (e.g., **62**, 45% yield, path e) [48], and 4-*N,N*-dimethylaminobiphenyl (**63**, 100% yield, path f) [39].

Recently, an optimization of the arylation process by using the environmental indexes of the EATOS method has been reported [77]. It was demonstrated that substitution of TFE with an acetonitrile–water mixture as the reaction medium markedly improves the eco-sustainability of the arylation process. Interestingly, the synthesis of biaryl **65** starting from mesylate **64** was found to be more environmentally benign if compared to other thermal or photochemical alternatives (Scheme 17.29) [77]. Notably, in this case the solvent was found to be the main contributor to the environmental impact.

An intramolecular formation of Ar–Ar bonds mimicking the phenyl cation chemistry was reported about 20 years ago. Thus, the triflate ester of the commercial pesticide 5-chloro-2-(2,4-dichlorophenoxy)

SCHEME 17.29

SCHEME 17.30

phenol (Irgasan DP300, **66**), when irradiated at 300 nm in acetone, gave 2,4,8-trichlorodibenzofuran (**67**) quantitatively. A triplet sensitized photolytic cyclization via triflate anion loss was invoked in this case (Scheme 17.30) [78].

Aryl sulfonates substituted with strong electron-withdrawing groups, such as fluorine, showed a peculiar chemistry when irradiated in neat aromatics (e.g., benzene or other various alkyl substituted benzenes). Thus, photolysis of a benzene solution of a pentafluorophenyl perfluoro- or a polyfluoroalkanesulfonate afforded the corresponding pentafluorobiphenyls in high yields [79]. The authors postulated an initial photoinduced electron transfer between the electron-deficient arene and the (alkyl) benzene. The mechanism is shown in Scheme 17.31 for the photoreaction between pentafluorophenyl triflate (**68**) and toluene (**69**). A radical ion couple was initially formed and then fragmentation of the radical anion generated a pentafluorophenyl radical that added to **69**^{•+}. Both *ortho*- and *para*-isomers of pentafluorophenyl toluene were thus formed with a poor regioselectivity but with a high mass balance (86%) [79]. Since neither benzylpentafluorobenzenes nor bibenzyls were obtained in this reaction, a proton transfer within the radical ion pair was ruled out due to the low basicity of **68**^{•-}.

SCHEME 17.31

17.3.2.1 Photo-Fries and Related Reactions

Originally, the photo-Fries reaction of sulfur-containing compounds was described by Havinga and coworkers. They evidenced that UV exposure of phenyl (or α -naphthyl) *p*-toluenesulfonates as well as phenyl methanesulfonate formed a mixture of rearranged *o*- and *p*-hydroxyphenyl sulfones, along with variable amounts of phenol [80]. The reaction is initiated by a photoinduced homolytic S–O scission with a radical pair formation (Scheme 17.32). The phenoxy radical thus formed can lead to phenol (by hydrogen abstraction) or, in alternative, recombination with the sulfonyl radical may give the two sulfone isomers via cyclohexadienone intermediates [81]. The product distribution was strictly dependent on the solvent used; being benzene the medium, the *ortho*-isomer was preferentially formed as shown in Scheme 17.32 for the case of phenyl benzenesulfonate (**70**) [81]. Interestingly, in alcoholic media the *para*-isomer was by far the main product.

A more clear-cut reaction was found if a complexing agent such as a β -cyclodextrin was either present in solution or formed a solid complex with the sulfonate ester [82]. In the former case, the irradiation of a β -cyclodextrin/water 1:5 solution of **70** led to the two photo-Fries adducts with no phenol formation. Noteworthy, in the photoreaction of the solid complex, a regioselective reaction took place, the *ortho*-rearranged derivative being the exclusive product [82].

The photo-Fries approach can be a mild, Lewis-acid-free, useful tool for the formation of Ar–S bond in heteroaromatic derivatives such as carbazoles. Accordingly, the photolysis in methanol of the mesylate ester of 9*H*-carbazol-2-ol (**71**) gave 1-(methanesulfonyl)-9*H*-carbazol-2-ol (**72**), 3-(methanesulfonyl)-9*H*-carbazol-2-ol (**73**) along with some hydroxycarbazole (**74**) in a ratio 6:2:1 (Scheme 17.33, part a). Moreover, the product distribution was not affected by changing the polarity of the medium [83].

8-Quinolinylnyl benzenesulfonates such as **75** likewise underwent homolytic cleavage of the S–O bond when photolyzed at 300–330 nm [84a]. The reaction was quite clean and both 8-quinolinol and benzenesulfonic acid were formed with negligible formation of by-products (Scheme 17.33, part b). The reaction involved the excited triplet state of **75** as confirmed by the high efficiency found in the benzophenone-sensitized photocleavage of this sulfonate. Also in this case, a radical couple was initially formed (see Scheme 17.32) and when a small amount of Et₃N was present in solution, its hydrogen transfer ability avoided the radical recombination, thus largely increasing the quantum yield of the reaction (up to 7–8 fold) [84a]. This protocol was then applied in the field of photocleavable biotin linkers that allowed the isolation of specific receptors by a photoinduced separation of the avidin matrix (as the avidin–biotin

SCHEME 17.32

SCHEME 17.33

complex) from the originally linked ligand–receptor complexes [84b]. The advantage of this approach is due to the mild conditions used, since the process took place without the need for any aggressive reagents.

Non-Fries pathways in aryl sulfonate photochemistry have led to acid generation, an interesting phenomenon widely used in microlithography [4]. These sulfonates (e.g., tris(methanesulfonyloxy)benzene) [85] were easily prepared, were soluble in a wide range of solvents (nonionic in character), and showed an UV absorption suitable for deep-UV exposure. Recently, Scaiano et al. [86] investigated the photochemical behavior of some phenyl sulfonates and the results are resumed in Scheme 17.34 (R = methyl, benzyl, tolyl).

Both H₂SO₃ and H₂SO₄ were released in solution as confirmed by ion chromatography analysis. These acids arose from the ensuing reactions of the radical pair that escaped from the solvent cage (Scheme 17.34). The scenario in Scheme 17.34 was further supported both by detection of the phenoxyl radical by laser flash photolysis experiments and by the presence of a large amount of non-Fries rearrangement products, that mainly accounted for the overall mass balance.

SCHEME 17.34

17.4 Conclusion

This chapter offers an overview of the different paths involved in the photochemistry of both phosphate and sulfonate esters. In some cases, despite the different ester moiety, the photochemistry of these compound shares a common mechanism as in the case of *o*-nitrobenzyl and coumarylmethyl derivatives. Nevertheless, phosphate and sulfonate esters have found application in different fields as inactive compounds that release the molecule of interest under very mild and selective conditions upon light exposure. Thus, phosphates were mainly used in biology (as “caged” compounds) because of the role of the released phosphate derivatives in living systems (e.g., ATP) [3b]. On the other hand, sulfonate esters have found a widespread application in material science, for example, in the field of photolithography as PAGs. The use of these esters in organic synthesis, however, is so far limited in scope. In fact an unsatisfactory effort has been devoted to this topic despite the promising application to the chemistry of phenyl cations, the virtually unexplored photoreactions of bi- and triaryl phosphates, the photo-Fries reaction of aryl sulfonates, and the $\text{ArS}_{\text{RN}}1$ process of aryl phosphates. Moreover, interesting photogenerated intermediates such as benzyl and alpha-keto carbocations deserve more attention for the formation of C–C or other C–X bonds.

18.1 Introduction

Carbocations play important roles as intermediates in organic chemistry. Stable and metastable ions are formed in acidic media [1] and since the lifetime of these intermediate species is often very short, time-resolved spectroscopy on the order of fs–ns is used to detect them. For this purpose, carbocations must be generated by laser impulses or lamp flashes of shorter duration than the time resolution of the spectroscopic equipment. A common method of photochemical carbocation generation is heterolytic bond fission of C–X bonds, whereby X is an electron-withdrawing group with proper nucleofuge properties [2]. Heterolytic photocleavage is favored in solvents of high polarity and with compounds yielding cations with low pK_R^+ values and having leaving groups X^- with low pK_a values for the conjugate acid. While the photoreaction may start from either the excited singlet or triplet state, singlet states are most often involved. The pathways of the photoreactions differentiate between adiabatic or diabatic bond fissions. The diabatic photoreaction is the dominant process, but in some cases, indications of the generation of excited carbenium ions were found [3,4]. In general, the efficiency of the photoheterolysis is high, resulting in high quantum yields [2].

Often heterolytic bond fission must compete with the homolytic bond fission, resulting in the generation of radicals that undergo reactions different from those of ions. The radicals generated by homolytic cleavage may react together by electron transfer, resulting in the same ionic species as obtained by direct heterolysis of the bond. The competition between both reaction pathways can be controlled by the solvent and the structure of the compound containing the fissionable C–X bond. The lifetime of the carbocation depends strongly on the ability of the positive charge to delocalize within the cationic moiety.

The term “stabilized carbocation” is a matter of definition. The primary focus of this chapter will be on carbocations with lifetimes longer than μs detectable by conventional flash photolysis or even generated using stationary lamps and steady state spectroscopy.

The electrophilic reactivity of carbocations is high. Protic solvents react with a cation in the order methanol > ethanol > water \gg trifluoroethanol (TFE) \gg 1,1,1,3,3,3-hexafluoroisopropyl alcohol (HFIP) [2].

Carbocations are pseudo acids according to Equation 18.1 with a corresponding equilibrium constant K_R .

A single linear free energy correlation ($\log k_W = f(\text{p}K_R)$) does not exist, but the data separate into families of structurally related ions. The reactivity follows the order 9-unsubstituted-9-xanthylum ion > phenyltropylium > diarylmethyl \approx 9-aryl xanthylum > triarylmethyl \approx 9-aryl-9-fluorenyl [2].

Like protic solvents, added nucleophiles such as oxyanions, thiolates, amines, and azides react with carbocations. Fast kinetics data were obtained using laser flash photolysis [1]. Ritchie proposed that the data could be satisfied by Equation 18.2:

$$\log(k/k_0) = N_+ \quad (18.2)$$

with

k and k_0 as rate constants for the combination of a carbocation and a reference nucleophile, respectively N_+ is a parameter dependent on the nucleophile and the reaction conditions [5]

This chapter, however, will not deal with the reactivity of carbenium ions as related to nucleophiles, but will focus on reversible photoheterolysis, which can be repeated several times. Because of the strongly different properties of the carbocations and their corresponding photoprecursors, applications such as photoswitches will also be considered. The generation of selected carbocations, their physical properties, their reactivities, and, if known, their applications will be included in the discussion.

18.2 Di- and Triarylmethyl Cations

Di- and triarylmethyl cations can be generated from their respective precursor acetates and *p*-cyanophenyl ethers by photoheterolysis in aqueous and alcoholic solvents (Scheme 18.1) [6–8]. Arylmethyl cations are less stable cations that are commonly encountered as reactive intermediates. For example, the lifetime of the triphenylmethyl cation in aqueous acetonitrile solution is only $4 \mu\text{s}$ [9]. The substituted arylmethyl cations have lifetimes ranging from 0.1 s for the tri-(4-MeOPh)methyl cation to 30 ns for the di-(4-methylphenyl)methyl cation. The formation of radicals competes with the generation of cations, and the presence of water in the solution counteracts the radical formation. Cation formation was not observed in dichloromethane solution. The formation of the cations in the ground state was complete after the 20 ns laser pulse. As expected, diarylmethyl cations are more reactive than triarylmethyl cations.

Steenken and colleagues [10] have extensively studied the photolytic bond fission of substituted diphenylmethyl halides in acetonitrile solution. Both diarylmethyl radicals and cations were obtained by laser flash photolysis at 248 nm. The two transient species can be easily differentiated by their UV-Vis spectra.

SCHEME 18.1 Generation and following reactions of arylmethyl cations.

While the radicals absorb in the region around 300 nm, the cations exhibit absorption bands around 450 nm. The radical $(4\text{-ClPh})_2\text{CH}^\bullet$ disappears in a second-order fashion, but the diphenylmethyl cation with substituents such as CF_3 , Cl, F, and H decay by first-order kinetics. However, the decay of stabilized cations such as $(4\text{-MeOPh})_2\text{CH}^+$ involves ion recombination and, therefore, second-order kinetics were observed. Photolysis of benzhydryl chloride including scavenger experiments of the products is shown in Scheme 18.2 [10]. The reaction of the cation with the solvent is reversible; therefore, by addition of water, the carbinol is the main product. Water reacts exclusively with the cation generated by the back reaction of the acetonitrile adduct. The ion combination was shown to progress by a diffusion controlled process.

The observed heterolysis: homolysis ratios correlate with the $\text{p}K_{\text{a}}$ values of the acids HX and not with the electron affinity of X. Whereas the quantum yields for homolysis (0.2–0.4) are independent of the nature of the substituent on the phenyl groups, those for heterolysis increase with increasing electron donor strength from ≤ 0.07 for CF_3 to 0.3 for OMe.

It is noteworthy that bond fission also occurs in the triplet state whereby the ratio of heterolysis to homolysis differs from that observed in the singlet state. Cations were formed exclusively in the ground state.

A consideration of the thermochemical aspects of bond cleavage makes the role of the solvent impressively clear: whereas photolysis (248 nm) in the gas phase is exothermic, photoheterolysis is not possible [10]. The degree to which heterolysis occurs as compared to homolysis depends on the extent of solvation of the incipient ions in the process of bond rupture. Because the solvation of ions requires a reorientation of the solvent molecules within ps, the heterolytic break must occur in the same time domain.

SCHEME 18.2 Formation and decay of diphenyl cations and radicals.

SCHEME 18.3 Deprotonation of an indicator by photogenerated hydroxyl ions.

SCHEME 18.4 Photocaged nitric oxide.

Solvation of charged species would also be necessary to enable homolytic bond breakage, followed by electron transfer between the radicals. Therefore, based on the identity of the products, direct heterolysis and the electron transfer pathway cannot be distinguished.

18.2.1 Caged Hydroxyl Ions and Nitric Oxide

Like halides, triarylmethyl alcohols are also able to produce the corresponding cation whereby a strong base OH^- is released, thus causing a pH increase [11–13].

The stability of the cation controls the rate of recombination. Therefore, the lifetime of the hydroxide ion generated by photolysis of trityl alcohol is too short to be of practical use [11]. Improved results were obtained in studies using Malachite green, and the increased pH value was maintained for seconds [12].

The photolysis of the ammonium salt **1** (Scheme 18.3) in aqueous solution at pre-pulse pH = 10.9 resulted in the heterolytic cleavage of the carbinol with a rate constant greater than 10^8 s^{-1} [13]. The multiphasic decay of the transient absorbance at 633 nm was associated with recombination reactions of the carbocation with hydroxide from the solution, but the source of the heterogeneity extending from the nanosecond timescale to the tens of seconds is not clear. The hydroxide ions photogenerated at neutral pH were shown to deprotonate the pH indicator bromoxyleneol, as reflected in the rise of the absorbance at 633 nm.

An irreversible C–O bond break occurs upon photolysis (390 nm) of compound **2** (Scheme 18.4).

The reaction can be used to liberate nitric oxide by light [14]. Both NO and the carbocation are expected to inhibit or encourage the proliferation of tumors depending on the dose. It has also been shown that the carbocation generated by photolysis of **2** is scavenged by guanosine.

18.3 Fluorenyl, Dibenzosuberonyl, and Xanthyl Cations

The introduction of a bridge between the phenyl groups of diphenylmethanol should result in the generation of more planar cations by photolysis. However, the lifetime of the resulting cations is not increased compared with the corresponding diarylmethyl radicals. On the contrary, the fluorenyl cation is extremely short lived.

18.3.1 Fluoren-9-yl Cation

Electronically excited 9-fluorenol **3** (Scheme 18.5) undergoes homo- and heterolytic cleavage of the C–O bond [15–19]. The bond-breaking process is strongly influenced by the solvent. As for the arylmethyl cations (see previous paragraphs), the solvation of the incipient ions must be very rapid so that the ionic path is already preformed by the solvent; accordingly the solvent must play an active part in the early stages of the cleavage process [20].

Indeed, the rate of decay of the excited state of 9-fluorenol in THF was quenched by addition of HFIP with a rate constant of $\sim 2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$. Probably, this is caused by a chemical reaction in which the excited state acts as a Brønsted base; water, at levels of 1.2%–2.0%, reduces the singlet lifetime from 160 ps in neat MeCN to 50–60 ps [20]. In all solvents (except for HFIP, TFE, and water) the 9-fluorenyl radical is formed from the excited singlet state. The first half life of the radical is in the range 0.5–1 μs . In HFIP, TFE, and H_2O , the transient absorption spectrum peaks at 515 nm and differs from that in other solvents. The absorption spectrum can be assigned to the 9-fluorenyl cation whose lifetime in HFIP is 30 ms and 1 ns in TFE. The fluorenyl cation **4** was also observed in water, as detected by a strong transient at 515 nm with a lifetime of only 15 ps. In water solutions, the only photoreaction is heterolysis. In contrast, in methanol both homolysis and heterolysis can occur.

In H_2O at very early times after the laser flash, the absorption maximum of the cation band lies at $<450 \text{ nm}$. The redshift of the band to 515 nm is attributed to the solvation of the initial “naked” cation or to the contact ion pair (see Scheme 18.5).

In accord with Scheme 18.5, 9-fluorenol is photostable in aqueous solution.

The solvent has a large influence on both the ionization and dissociation, but affects each parameter differently. Ion pair formation, the first step, strongly depends on the ability of the solvent to function as an electron acceptor or a donor as reflected in the Kosower Z-value or the Reichardt E_{T} solvent parameters. The dissociation of the contact ion pair depends on the ability of the solvent to lower the strong attraction between the ions leading to free solvated ions. For this function of the solvent, the dielectric constant is important. With respect to the first step, the proton transfer properties of the solvent may drive the C–O bond cleavage into the heterolytic direction as symbolized in Scheme 18.5. In contrast to hydration, proton transfer is sufficiently rapid to contribute in the transient state of the dissociation [20].

SCHEME 18.5 Kinetic scheme of the 9-fluorenol photolysis.

18.3.2 9-Arylfluoren-9-yl Cations

9-Aryl-9-fluorenol undergoes a very efficient photoheterolysis in TFE and H₂O/MeCN 4:1 solutions. Quantum yields are on the order of 0.5–0.8, and are relatively insensitive to the nature of the substituent in the 9-aryl group [21]. In contrast, triphenylmethanol undergoes an inefficient photolysis under the same conditions (248 nm excitation wavelength).

The lifetimes of the 9-aryl-fluoren-9-yl cations are much longer than that of the unsubstituted fluoren-9-yl cation. The rate constants of the exponential decay of 9-aryl-fluoren-9-yl cations range from 2×10^2 to $1 \times 10^5 \text{ s}^{-1}$ in TFE and 2×10^5 to $5 \times 10^7 \text{ s}^{-1}$ in H₂O/MeCN. The 9-aryl substituent significantly retards the reactivity of the fluoren-9-yl cations. Kinetic stabilization by the aryl substituent may be attributed to both resonance and steric effects. Compared with other benzylic-type cations, the general trend is observed that the more inherently stable the cation, the smaller the effect of an additional phenyl substituent. Because the fluoren-9-yl cation is inherently unstable, substituents in the 9-aryl-group have a significant effect despite the fact that the phenyl ring is twisted out of the plane by probably more than 30°. The greater polar interaction observed for *p*-substituents may be a compensation for the smaller resonance interaction between the substituted phenyl group and the positive charge in the 9-position caused by the twisting of the aryl ring [21].

18.3.3 9-Acyl-Fluoren-9-yl Cations

Fluoren-9-yl cations are not only stabilized by aryl groups but also by electron deficient substituents such as carbonyl and thiocarbonyl groups [22,23]. The lifetime of **6** is about 1 ms in HFIP.

Absolute rate constants for the reactions of cations **6** with methanol in HFIP solution reveal that the thiocarbonyl-substituted cation reacts slower than the cation substituted with an ester group (Scheme 18.6). According to the transient absorption spectrum of **6**, stabilization is supported by the open resonance structures rather than by a cyclic oxyranyl cation.

18.3.4 Intermediates of Photopinacol Rearrangement

Fluoren-9-yl cations are also intermediates of the photochemical pinacol rearrangement [24,25].

The cation **10** primarily generated by photoheterolysis was detected by transient absorption spectra showing absorption bands at 505 and 700 nm. The transient observed at 350 nm may be associated with the ketyl radical **9** yielding the byproduct fluorenone (Scheme 18.7).

The fluorenol **11** (Scheme 18.8) was photolyzed in order to explore the possibility of hydride transfer within the cation [26].

However, it was demonstrated that such hydride migration does not occur. The lifetime of the transient cation **12** is within 14 μs in TFE, a significant increase in lifetime as compared with the parent fluoren-9-yl cation. In this case, steric crowding also contributes to the enhanced lifetime. Cation **12**

SCHEME 18.6 Photosolvolytic reaction of acyl-substituted chlorofluorene.

SCHEME 18.7 Photopinacol rearrangement in HFIP.

SCHEME 18.8 Photoreaction of the fluorene 11.

reacts efficiently with nucleophiles such as Br^- , MeOH, EtOH, i-PrOH, and H_2O with bimolecular quenching rate constants from 9.5×10^8 (Br^-) to $5.9 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ (i-PrOH).

18.3.5 Dibenzosuberanol

The expansion of the π -system of the fluorene 3 leads to the 5H-dibenzo[a,d]cyclohepten-5-ol **16** (Scheme 18.9). In laser flash experiments, the formation of the cation **17** was detected by its transient absorption spectrum [27].

SCHEME 18.9 Processes observed by laser flash photolysis of the alcohol **16** in TFE.

The intermediate cation **17** has a lifetime $>100\mu\text{s}$ in TFE solution, much longer than that of the cation **4**. Azide anions quench the cation with a quenching constant $1.1 \times 10^9\text{s}^{-1}$. Although there may be some adiabatic formation of **17**, the majority of cations were diabatically formed. The formation of radical cations was observed at high laser doses via photoejection of electrons.

18.3.6 Xanthenol

Photoexcited 9-phenyl-9-xanthenol **18** undergoes heterolysis with a quantum yield of 0.6 in water/MeCN 4:1 [7]. The parent xanthen-9-yl cation is formed with a quantum yield 0.8.

Relative yields of cation **19** and radical **20** (Scheme 18.10) strongly depend on the solvent (Table 18.1) [28]. The cation is directly formed in the ground state. In contrast, besides the diabatic pathway, about 1% adiabatic, water-catalyzed formation of the excited cation in water/methanol solution was reported [28]. The 9-phenyl-xanthen-9-yl cation **19** (Scheme 18.10) decays in water/MeCN 4:1 with a first-order rate constant of 23s^{-1} . In water/acetonitrile 1:1, a complex decay of **19** was observed suggesting that the recombination of **19** with HO^- competes with its reaction with water (Scheme 18.10) [28].

Due to the high stability of **19** as reflected by its long lifetime in water/MeCN 4:1, the reactions of nucleophiles such as water with **19** are relatively slow ($k_{\text{solvent}} = 2.3 \times 10^4\text{s}^{-1}$). Interestingly, the rate constants of photoexcited **19**^{*} are much higher than those of the ground state **19**. Double laser experiments

SCHEME 18.10 Photoheterolysis and -homolysis of the alcohol **18**.

TABLE 18.1 Relative Yields of Cation **19** and Radical **20** in the Course of 248 nm Laser Flash Photolysis in Various Solvents

Solvent	Relative Yield	
	19	20
H ₂ O/MeCN 1:1	0.5	<0.1
H ₂ O/MeOH 1:1	1.0	—
MeOH	0.2	0.5
MeCN	<0.05	1.0
<i>n</i> -Heptane	—	1.0

SCHEME 18.11 Pixyl and S-pixyl groups as photocleavable protecting groups.

provided evidence for the chemical quenching of the singlet state of **19** [28]. The rate constants of **19**^{*} with water and MeOH in acetonitrile solution are 3.3×10^7 and $9.7 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, respectively.

18.3.7 Photocleavable Protecting Groups

The 9-phenylxanthyl (pixyl) and 9-phenylthioxanthyl (S-pixyl) moiety can be used for protecting groups of nucleosides that are cleavable under neutral conditions by light (Scheme 18.11) [29,30].

18.4 Acridinium Ions

18.4.1 Photoheterolysis of Acridanes

9-Phenyl-9-hydroxy-9,10-dihydroacridine (9-phenyl-9-hydroxyacridane) **21** undergoes efficient photoheterolysis in various alcohols with quantum yields ranging from 0.4 (i-PrOH) to 0.8 (EtOH) [31]. The rate constants of photoheterolysis were calculated to be $>10^9 \text{ s}^{-1}$.

The formation of the acridinium ion **22** (Scheme 18.12) occurs diabatically from the excited singlet state. Although the recovery of the acridane by the nucleophilic attack of the alcohol used was not demonstrated, it was shown that the cation completely disappeared in the presence of propanol with a solvolysis constant $7 \times 10^{-3} \text{ s}^{-1}$.

SCHEME 18.12 Photoheterolysis of the acridane **21** and the pseudo base equilibrium.

The formation of hydroxide ions by photoheterolysis of **21** in MeCN/water (3:1) has been observed indirectly by the increase of the pH value to about 12 during the photolysis [12]. A pH value above 11 was maintained for more than 10 h, and illustrates an example of photocaged hydroxyl ions. The lifetime of the acridinium ion is exceptionally long and supports the high stability of the acridinium ion under solvolytic conditions.

If a completely reversible photoheterolysis and thermal recovery of the acridane occurs, a photochromic system can be developed. Acridanes are colorless compounds with absorption bands around 320 and 280 nm, but the acridinium compounds absorb light from 430 to 550 nm, depending on the 9-aryl substituent on the acridinium ion.

The acridanes are pseudo bases according to Equation 18.3. Kinetic data obtained by stopped flow spectrometry [32] showed that substituents at the 9-position reduced the rate of hydroxide ion attack at C-9. The C-9 substituent of **22** influences the stability of the acridinium ion in aqueous solution mainly via unfavorable *peri* interactions between the aryl group and the C-1 and C-8 protons. For 9-aryl substituents, possible contributions from resonance interaction must also be considered. However, this interaction must be quite small because ΔpK_R^+ between the 9-phenyl and the 9-(4-dimethylaminophenyl) acridinium ions is only 0.5; the stabilization by the dimethylamino group is only 0.7 kcal mol⁻¹ [32]. The angles between the planes of the aryl substituent and the acridinium plane are more than 40°, and account for this minor effect on stabilization. On the other hand, the electronic absorption spectra of the 9-(4-dimethylaminophenyl) acridinium ion shows pronounced bathochromic shifts relative to the 9-phenylacridinium ion. Strong electron donating aryl groups change the nature of the first excited singlet state [33]. While the long-wavelength absorption of 9-phenylacridinium ion is determined by the locally excited state in the acridinium moiety, the long-wavelength absorption of 9-(4-dimethylaminophenyl) acridinium ion is attributed to a delocalized charge-transfer state. Charge shift species arising from the intramolecular electron transfer have been identified through observation of redshifted fluorescence emission bands and the appearance of radical and radical cation transients [34]. The data reveal that there is a significant electron coupling between the acridinium moiety and the aryl group.

Figures 18.1 [35] and 18.2 [36] demonstrate the uniform photoreaction observed upon irradiation of two acridane derivatives having aryl substituents of different electron donor strengths (Scheme 18.13).

The thermal recovery of acridane **23** after irradiation obeys a first-order kinetics with a rate constant $8.3 \times 10^{-4} \text{ s}^{-1}$ (lifetime of the acridinium ion **24** = 20 min). UV-Vis absorption spectra recorded at different time after irradiation show the same isosbestic points as observed in the photoreaction

FIGURE 18.1 UV-Vis spectra recorded after consecutive irradiation of acridane **23** (0, 1, 3, 11 min, 313 nm) in EtOH/MeCN (5:1) solution.

FIGURE 18.2 UV-Vis spectra recorded after consecutive irradiation of acridane **25** (20 s ... 8 min, 313 nm) in acetonitrile solution.

SCHEME 18.13 Photoheterolysis of compound **23** and **25** and thermal back reaction of the acridinium ions.

SCHEME 18.14 Equilibrium between acridane and acridinium ion in methanol solution.

revealing the presence of only two species: the acridinium ion **24** and the acridane **23**. According to the pseudo-first-order kinetics the acridinium ion reacts with the alcoholic solvent, assisted by the ethoxide ion that scavenges the proton (Scheme 18.13). The photoreaction using conventional lamps must compete with the thermal back reaction. Therefore, the maximum turnover depends on the light intensity.

Irradiation of acridane **25** was performed in acetonitrile solution. The lifetime of the acridinium methoxide in this aprotic solvent is more than 10 h, and the complete recovery of the acridanes was not observed. However, both in air-saturated acetonitrile and in argon-purged solutions only the characteristic absorption bands of the acridinium ions were observed. There were no indications that radicals had been formed via homolytic bond fission. Accordingly, quantum yields of photoheterolysis were determined in acetonitrile solution. For example, the quantum yield of photoheterolysis of the acridane **23** is 0.5 [35].

Because of the reversibility of the acridane/acridinium system in solvents containing at least 5% alcohol, the photochromic system can also represent a molecular photoswitch. The properties of acridanes and acridinium alkoxides are markedly different with regard to their shape, their basicity, and their electronic properties. The photoheterolysis transforms an electron donor into an electron acceptor, and this switching can be used to design photoswitchable rotaxanes as will be discussed in the following.

Acridanes possessing 9-aryl substituents with electron donor character are stable in EtOH and PrOH, but are ionogenic compounds in methanol solution (Scheme 18.14). Therefore, applications of photoheterolysis are restricted to solvents containing EtOH or PrOH.

18.4.2 Acridanes on Gold Nanoparticles

Esterification of **27** with liponic acid leads to **29** (Scheme 18.15), which is able to bind onto gold surfaces. Gold nanoparticles (GNPs) protected by dodecanthiol can be loaded with **29** by the exchange method [37]. Photoheterolysis of **30** in acetonitrile/MeOH is observed, but a complete recovery of acridane **30** by the thermal attack of the methoxide ion on the acridinium ion on the GNPs could not be observed.

18.4.3 Acridane Photoswitch for Switchable Rotaxanes

Rotaxanes are mechanically coupled molecules consisting of a wheel and an extended molecular axle, and these two parts are freely movable relative to each other. These nanostructures are promising candidates for the development of molecular machines [38,39]. The position of the wheel is governed by the interaction between the so-called recognition stations present in both the wheel and the axle. If at least two stations are present within the axle, the dynamics of the ring translation along the axle depends on the presence of identical or different stations. Degenerate rotaxanes contain two identical stations and

SCHEME 18.15 Immobilized acridane **30**.

the wheel shuttles between them by Brownian motion. The activation energy of this shuttle movement depends on both the chemical structure of the axle and the distance between the two stations [40]. If the energy of the interaction between the two different stations and the wheel is sufficiently large, the wheel will exclusively reside on the station that supplies the highest energy gain for the wheel–axle interaction. In switchable rotaxanes, the energy of interaction for the recognition station and the wheel is drastically weakened by an external stimulus. Accordingly, the interaction with the second, unchanged station is favored and the ring moves to this station and the so-called co-conformation is completely rearranged by Brownian motion. Solvents, chemicals, electrons, and photons are able to act as stimuli. Using light is advantageous because no side products of the switching process are evolved and because light action is addressable. The reset can take place either photochemically or thermally.

Photoresponsive rotaxanes based on the photoheterolysis of an acridane unit, which is at the same time a bulky end group, has been developed (Scheme 18.16) [35,36]. The tetracationic wheel cyclobis(paraquat-4,4'-bisphenylene) (CBQT^{4+}) is a strong electron acceptor. Accordingly, recognition stations within the axle should be the electron donors. Besides charge-transfer π -stacking, edge-to-face interactions and C–H–O hydrogen bonds also contribute to the interaction between the wheel and the axle stations. In rotaxanes **31** and **33**, the acridane stations and the evasive stations B must compete for the interaction with the wheel. Although the aryl groups present at the 9-position of the acridane of **31** and the station B are very similar, the wheel exclusively resides on station A because an additional edge-to-face interaction is only possible with the acridane station. The position of the wheel can easily be determined by ^1H -NMR, ^{13}C -NMR, and two-dimensional NMR spectroscopy such as ROESY. The acridane units in the rotaxanes undergo photoheterolysis resulting in the acridinium rotaxanes **32** and **34** (Scheme 18.16). The formation of the acridinium moiety is evidenced by transient UV-Vis absorption spectra. Due to the generation of a positive charge, the tetracationic wheel is repelled and moves to the evasive station B, driven by Brownian motion. Because of the inner filter effect of the absorption by the wheel and the low-lying charge-transfer state formed by the interaction between the acridane station and the wheel, the quantum yield of photoheterolysis is drastically reduced to ≤ 0.1 for **31** and ≤ 0.05 for **33**. This process is a general disadvantage of systems based on charge–transfer interaction. The lifetime of

SCHEME 18.16 Two photoswitchable rotaxanes based on photoheterolysis.

the acridinium state of the rotaxanes depends strongly on the solvent used, ranging from about 100 s in neat methanol to several hours in acetonitrile with 10%–20% ethanol. In every case, there is enough time for ring movement. Owing to the reaction of the acridinium moiety with the alcohol assisted by the methoxide, the acridane is recovered and the wheel moves back to station A. This cycle can be repeated without fading of the system.

The drawback of reduced efficiency of photoheterolysis caused by the charge-transfer state is circumvented in rotaxanes with two acridane stations such as in **35** (Scheme 18.17). Because only one of the two acridane stations can be occupied by the wheel, the free acridane station is exclusively excited to give the acridinium station. Now, the type of movement is changed. In rotaxanes such as **31/32** only one of the two stations is always occupied, and thus, the wheel does not move. In the degenerate rotaxane **35**, the wheel

SCHEME 18.17 A rotaxane with two acridane units.

translates from one acridane station to the other. By photoheterolysis of only one of the two acridane stations, the wheel will remain at the unchanged station, thereby stopping the wheel movement [41].

It is noteworthy that the interaction of the wheel with the acridane units in rotaxanes **31**, **33**, and **35** protects the acridane moiety from solvolysis. In contrast to compounds **23** and **25** (Scheme 18.13), the acridinium rotaxanes react in diluted solutions of protic solvents to give the corresponding acridane rotaxanes [35,36]. This behavior is attributed to the energy gained by the interaction between the wheel and axle.

18.4.4 Photoswitchable Hosts with Acridane Subunits

The change of electronic properties and of the molecular shape by switching from acridanes to acridinium ions can also be used to switch the complexation properties of hosts such as calixarenes [42–44] and crowns [45].

The change in shape between the acridane and acridinium moieties results in the respective opening and closing of the inner cavity of calixarenes (Scheme 18.18) [42].

SCHEME 18.18 Blocking of the cavity of a calixarene by photoheterolysis.

SCHEME 18.19 Uptake of Na^+ ions induced by photoheterolysis of acridane calixarene **39** in acetonitrile solution.

SCHEME 18.20 Uptake of K^+ ions induced by photoheterolysis of calixarene **41** in acetonitrile/EtOH 4:1 solution.

SCHEME 18.21 Decomplexation of the pseudorotaxane **43** by photoheterolysis of the acridane host in acetonitrile solution.

Acridane and acridinium ions, respectively, at the wide rim of calix[4]arenes influence the complexation properties of the glycol chain at the narrow rim, as illustrated in Scheme 18.19 [43]. Against all expectations, the acridinium-substituted calixarene **40** binds Na^+ ions more strongly than the corresponding acridane-substituted host. This process also holds true for calixarenes **41** and **42** (Scheme 18.20).

In contrast to **41**, the complexation of K^+ by **42** occurs in acetonitrile containing 20% ethanol. The latter solvent is necessary to support the thermal back reaction, thus making the system reversible. The complexation of different alkali ions by acridane- and acridinium-substituted calixarenes such as **41** and **42** has been studied by isothermal calorimetry. According to the results obtained for **42**, two host molecules are needed for complexation of one K -ion (Scheme 18.20) [44].

Furthermore, the complexation behavior of the crown **44** is changed by transformation into the acridane-substituted host [45]. The pseudorotaxane **43** is dethreaded by photoheterolysis in acetonitrile solution (Scheme 18.21). The slow recovery of the rotaxane can be followed by NMR spectroscopy.

18.5 Aryltropylium Ions

18.5.1 7-Methoxy-Aryl Cycloheptatriene as Precursors of Aryl Tropylium Ions

Aryltropylium salts such as **46–48** (Scheme 18.22) are converted into aryl-methoxy-cycloheptatrienes by reaction with methanol, resulting in three isomers (Scheme 18.22).

Cycloheptatrienes **49–51** contain the leaving group methoxide and the aryl substituent, which stabilizes the tropylium ion. Nevertheless, all tropylium ions react nearly quantitatively with methanol without the support of a base [46]. Laser flash photolysis of mixtures of the three isomers of **49–51** resulted in the formation of the corresponding aryltropylium methoxides both in methanol and acetonitrile solution. The transient UV-Vis absorption spectra corresponded to the absorption spectra recorded with stable tropylium salts. Simultaneously with the transient absorption, a photocurrent was formed, indicating the generation of ionic species. The quantum yield is 0.1 for the formation of **48** in MeOH solution. At constant absorbed dose, the transient absorption of **48** is much weaker in MeCN than in MeOH,

SCHEME 18.22 Formation of isomeric aryl-methoxy-cycloheptatrienes **49–51** and their photolysis.

SCHEME 18.23 Photoheterolysis of isomeric 7-methoxy-diaryl-cycloheptatrienes in methanol solution.

indicating different ion yields in the two solvents. Additional transient absorptions by radicals were not observed. The lifetimes of the transient aryltropylium methoxides are in accord with the electron donating power of the aryl substituent (**46**: 190 μ s, **47**: 270 μ s and **48**: 3 s). The lifetimes can be elongated further by introduction of a second aryl group into the seven-membered ring (see Scheme 18.23) [47].

The aryltropylium methoxide **48** generated by laser flash photolysis of the isolated isomer **51c** disappeared by second-order kinetics because the direct combination of the ions takes place. In contrast, using a solution of **48** in MeOH without the addition of a base, the disappearance followed first-order kinetics exactly. In this case, the tropylium ion reacts with the solvent, because the methoxide ion is scavenged by protons formed in the reaction of **48** with methanol (see Scheme 18.22).

The switch cycle with **51c** can be repeated several times. However, irradiation of **51c** with 10 laser flashes (5.7×10^{-5} E l⁻¹ flash⁻¹, flash duration 20 ns) reduces the intensity of the transient optical absorption due to the presence of **48** by a factor of 2. It is worth noting that 17 flashes (1×10^{-4} E l⁻¹ flash⁻¹) reduce the intensity of the transient absorption of the tropylium ion **53b** to 50% [47]. Diaryl-substituted 7-methoxycycloheptatrienes allow an increased number of cycles.

The observed fading of tropylium ion generation is attributed to the competing hydrogen shift that shifts the methoxy group from the sp³-C to sp²-C, thus inhibiting the photoheterolysis.

The photochemistry of arylcycloheptatrienes is determined by a sigmatropic hydrogen shift and electrocyclization [48]. Therefore, it is astonishing that photoheterolysis is able to compete with these pericyclic reactions. The photochemistry of compound **51c** has been studied in more detail [49]. Steady-state irradiation of **51c** with light of 365 nm in acetonitrile solution resulted in the formation of the isomeric compound **51d** (Scheme 18.24). Isosbestic points observed with UV-Vis spectra recorded after consecutive irradiation revealed a uniform reaction. The formation of tropylium ions could not be observed with steady-state methods. However, neither could a uniform reaction be observed in methanol solution, indicating the occurrence of a second reaction, which is attributed to photoheterolysis followed by thermal reactions leading to various isomers from **51c**. The quantum yield of tropylium ion formation depends on the hydrogen bond capacity of the solvent ($\Phi_{\text{MeOH}} > \Phi_{\text{ethyleneglycol}} > \Phi_{\text{EtOH}} > \Phi_{i\text{-PrOH}}$).

Transient absorption spectra measured with methanol and acetonitrile solutions of **51c** using the pump-supercontinuum-probe technique [50] allowed the examination of reaction events during the time period immediately after the absorption of the 150 fs laser pulse [51]. Factor analysis of the spectra in the range 340–650 nm pointed only to two major components, which can be assigned to the excited singlet state of **51c** and to processes of two-photon absorption and relaxation of highly excited states. The lifetime of the first excited state is 440 ± 44 ps. This value corresponds to the rate of the formation of

SCHEME 18.24 Photochemistry of compound **51c**.

the tropylium ion **48** (see Figure 18.3). The assignment of the component with the 440 ps lifetime to the first excited state was confirmed by fluorescence decay measurements ($\tau = 480 \pm 50 \text{ ps}$).

The formation of **48** by photoexcitation of **51c** in acetonitrile was not observed.

18.5.2 Rotaxanes with the Cycloheptatriene Switch

Like the acridane switch, arylcycloheptatrienes with the methoxide leaving group convert an electron donor into an electron acceptor; the boat-like structure of the cycloheptatriene is transformed into the planar seven-membered ring of the tropylium ion and the color changes from colorless to blue (in the case of **51c**) [52]. Accordingly, photoswitchable rotaxanes were designed with **CBQT**⁴⁺ as the wheel and with axes containing the cycloheptatriene switch in the center. Two examples are shown in Schemes 18.25 [53] and 18.26 [54].

Rotaxanes **54** and **56** also are based on charge transfer interactions between the cycloheptatriene stations and the tetracationic wheel. Therefore, the quantum yield of photoheterolysis of the 7-methoxy-diaryl-cycloheptatrienes is diminished to about 0.01 due to the higher rate of non-radiative decay of the excited state of the rotaxanes resulting from the existence of low-lying charge-transfer states. On the other hand, the hydrogen shifts as photoreactions competing with heterolysis are quenched in the rotaxanes, allowing more switching cycles of rotaxanes compared with the corresponding free molecular axle molecules. The lifetime of the rotaxane **55** is 15 s, a value significantly higher than that of **48**. Certainly, the lifetime is long enough to allow wheel movement from one station to another [55].

18.6 Retinyl Cation

Retinol is one of the chromophores of rhodopsin, and *trans-cis*-isomerization and heterolytic bond cleavage play important roles [1]. The quantum yield of photoheterolysis of **58a** (Scheme 18.27) was estimated as 0.1 and that of **58b** as 0.5 in methanol [56].

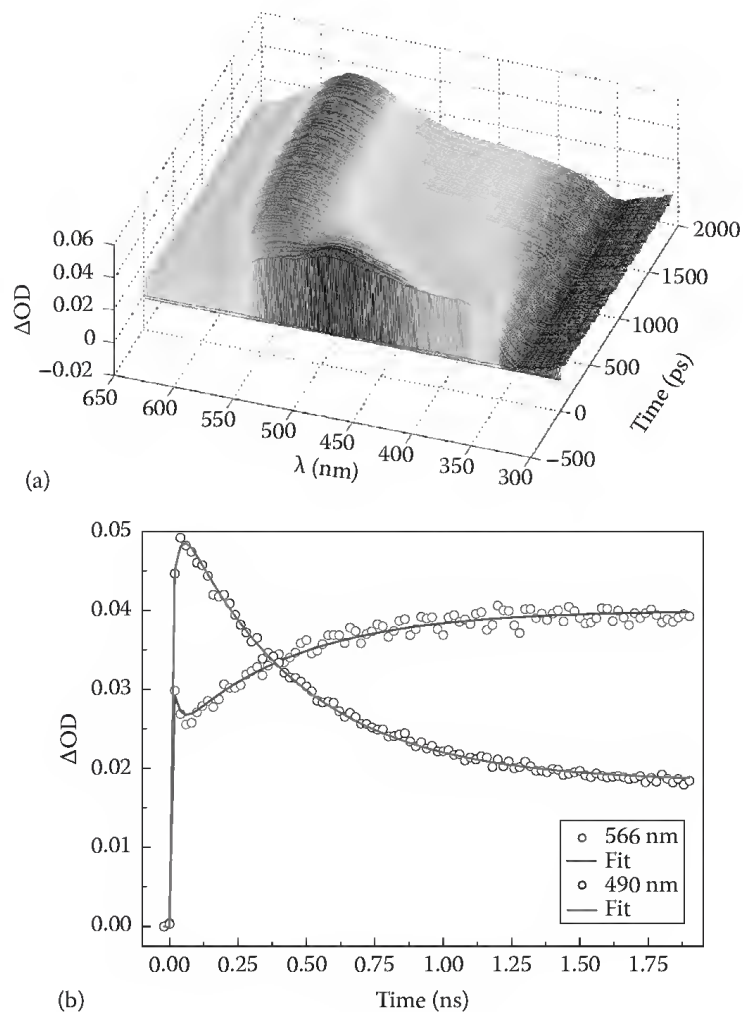

FIGURE 18.3 (a) (See color insert.) Three-dimensional representation of transient absorption spectra of **51c** in methanol recorded after excitation at 260 nm. (b) The transient absorption decays of **51c** in methanol measured after excitation at 260 nm—green line decay of the first excited state (490 nm); red line formation of **48** (566 nm).

SCHEME 18.25 Switching the position of the wheel.

SCHEME 18.26 Photoswitchable rotaxane 56.

SCHEME 18.27 Generation of the retinyl cation by photoheterolysis.

SCHEME 18.28 Photoheterolysis of 1,3-dithiolanes.

The lifetime of the cation is 20 μs in methanol [57]. The transient absorption of the retinyl cation peaking at 600 nm is blueshifted in viscous solvents such as 1-decanol in the time range of 1 ns [58]. Thus, it was concluded that the primary heterolysis product was the contact ion pair. The heterolysis process is monophotonic. In contrast, the formation of the radical cation in methanol is a two-quantum process.

18.7 Dithio Carbocations

Sulfur atoms adjacent to positively charged carbon centers strongly stabilize the cations, thus shifting the lifetime into the second range (Scheme 18.28).

Transient UV spectra peaking at 342 nm in water/EtOH (1:1) were recorded in time intervals on the order of milliseconds. Time-dependent absorbance changes follow a pseudo-first-order decay with a rate constant of 0.56 s^{-1} [59]. The leaving group thiolate of **63** is a better nucleophile than water. Accordingly, in aqueous solution second-order kinetics were observed, indicating the ion combination in this case.

18.8 Concluding Remarks

The field of photolytic generation of carbocations has been developed over the last four decades, with the reactivity of carbocations with nucleophiles being the main focus of research. However, some examples of reversible heterolysis have been presented in the last decade. Reversible dissociation of suitable precursors results in very stable cations with lifetimes on the order of seconds to minutes. Such carbocations together with their precursors represent photoswitches. The following switchable properties are of interest:

1. Because the leaving groups mainly are strong bases, the pH of solutions is increased for a limited time, and the pH increase can be localized by laser flashes. This pH jump may be applicable for base-catalyzed polymerization or for base-catalyzed reactions. Up to now, studies with caged alkoxide bases have not been performed.
2. The switch from an electron donor to an electron acceptor has been used to govern the co-conformation of rotaxanes and the complexation properties of host molecules. However, further developments of applications are expected.
3. Because photoheterolysis results in the formation of two solvated ions, the conductivity of solutions can be switched. No applications of this effect are yet known.
4. Just the precursors of most stable carbocations are photochromic systems, and their colors are tunable by substituents. The lifetimes of the colored species are tunable by the solvents used for heterolysis.
5. At present, there have been no studies of photoheterolysis in polymers.

19.1 Introduction

19.1.1 Overview

The formation of carbon–carbon bonds is the key process in the synthesis of the vast majority of organic molecules, and, understandably, an enormous range of methods for carrying it out is currently available. As a result of developments in synthetic methodology over the last 20–30 years, many of these now involve C-radicals [1]. Although such methods are synthetically very valuable, their use is problematic as the generation of the C-radicals generally involves the use of tin compounds, peroxides, or azo compounds, all of which are undesirable in terms of clean/green chemistry and of the concept of sustainability in general. This chapter explores the synthetic utility of photochemical intermolecular H-abstraction as an alternative method of generating C-radicals for use in C–C bond formation (Scheme 19.1). This process is one of a number of related photochemical processes that tend to be grouped together under the general heading of “photocatalytic methods.” The synthetic potential of these methods has been recognized in a recent comprehensive review [2], although they have been largely ignored in an otherwise

SCHEME 19.1

thorough description of the role of C–H transformations in organic synthesis [3]. The particular focus of this chapter is on systems in which C-radical formation involves intermolecular H-atom abstraction from a C–H bond; intramolecular H-abstraction processes are only considered when they are relevant to a discussion of related intermolecular reactions. Photoreactions that involve a single electron transfer (SET) have also been excluded; details of such processes, which include the generation of α -aminoalkyl radicals, are available elsewhere [2]. Photochemical C-radical forming reactions involving peroxides, tin compounds, or γ -radiation make up a third group that are not dealt with in this chapter.

The reactions considered fall into two different classes. In one of these the radical generation process involves the intervention of what is here called a photomediator, X, which until recently was most often an aromatic ketone (Scheme 19.1). The terms “photoinitiator” and “photocatalyst” have also been used to describe the role played by this agent, but as there is rarely evidence for a chain mechanism and as most reactions of this type involve quantities of X that are well in excess of what could reasonably be called “catalytic,” the term “photomediator” is preferred*. Once generated, these C-radicals are indistinguishable from those generated in any other way, for example, using peroxides. They are in general nucleophilic in character and if generated in the presence of a molecule containing an electron-deficient multiple bond that includes at least one C-atom, conjugate addition will lead to the formation of a C–C bond [4]. In reactions in the second class, no specific photomediator is added and instead it is the unsaturated substrate that, following excitation, abstracts a H-atom from the donor molecule. The term “direct” is used in this review to describe reactions of this second class.

In addition to avoiding the use of undesirable reagents, the method has a number of other advantages. It is atom efficient in the usual sense that all of the atoms in the reactant molecules end up in the product. The nature of the reaction allows molecules such as cycloalkanes and cyclic ethers, which are not functionalized in the normal sense and are most commonly encountered as solvents, to participate as H-donors. It also opens up different reaction pathways for molecules, such as in the case of a secondary alcohol, which reacts through its methine hydrogen rather than in the usual way through its hydroxyl group. In many cases, the photomediator is effective in significantly substoichiometric quantities [5,6] relative to the amount of the unsaturated reactant and so its involvement does not materially affect the atom efficiency of the process. An interesting property of the reaction system is that it can be driven by solar radiation [7], as two of the most widely used photomediators, benzophenone [8] and the polyoxometallate tetrabutylammonium decatungstate (TBADT) [9], absorb at approximately 350 nm, a wavelength that is available in the sunlight reaching the surface of the earth.

The approach also has its disadvantages such as the requirement that the H-donor is present in large excess, and thus must be removed from the product mixture. This effectively restricts the reaction to readily available H-donors of relatively low molecular mass, which can be recovered by distillation after the reaction is complete. The fact that the photomediators are not selective in terms of H-abstraction also precludes the use of large molecules with many different types of C–H bond. In some cases an efficient reaction requires the use of approximately stoichiometric quantities of the photomediator, partly because some, or indeed most of it, is rendered inactive as a result of ketyl radical recombination (Scheme 19.2). This again adds to the experimental difficulties associated with the isolation of the product. The problem of removing the photomediator and a desire to enhance the reaction system from the clean/green chemistry

* For a discussion of the use of these terms, see: Ref. [2, p. 2726].

SCHEME 19.2

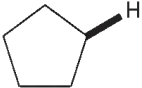

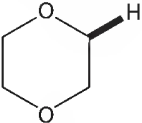

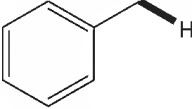

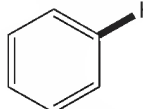

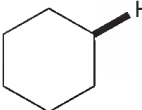

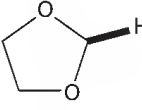

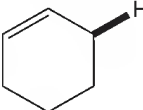

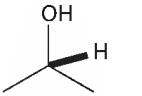

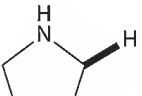

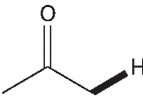

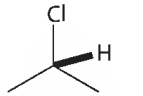

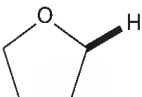

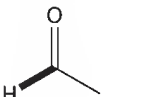

perspective have led to an interest in the use of supported photomediators, which can be removed by simple filtration after the reaction and recycled [8]. The introduction of TBADT, a photomediator that can be used in essentially catalytic quantities and that is effective with greatly reduced amounts of the H-donor [6], is a further indication that these problems can be, at least partially, ameliorated.

Aromatic ketones are widely used as photomediators and the mechanism by which they function (Scheme 19.2) provides an insight into the issues that are generically important for all classes of photomediators and facilitates a discussion of the factors relating to the behavior of the H-donor, photomediator, and unsaturated system. In addition, it underlines the fact that when most inefficient, the process requires at least one photon of light to complete the reaction cycle. However there is the possibility that the back H-transfer to the radical precursor of the product may involve a molecule of H-donor, RH, rather than the ketyl radical or its equivalent, and that as a result the process can assume the character of a chain reaction. The amount of photomediator required to achieve an efficient reaction is system dependent, suggesting that the contribution of a chain reaction to product formation also depends on the particular molecules involved. Although the possibility of developing reaction systems that are based on a chain mechanism is attractive, the evidence suggests that at best the chains involved are relatively short. The mechanism also emphasizes that if the back transfer of the H-atom is slow then recombination of the ketyl radicals can occur, leading to a removal of the aromatic ketone from the reaction cycle. The degree to which this process is a problem depends on the reaction system involved and the fact that it is not an option for photomediators such as TBADT is one of the major differences between aromatic ketones and such polyoxometallates, the two most widely used classes of photomediator.

19.1.2 Hydrogen Donors

Ketones, and in particular aromatic ketones such as benzophenone, are the most widely used photomediators. The similarity in the behavior of such ketones, in their (n,π^*) excited state, and that of alkoxy radicals was first pointed out over 40 years ago [10] and still remains the basis for rationalizing the photochemistry of ketones in that particular excited state. Although there is evidence to suggest that H-abstraction from relatively weak C–H bonds (bond dissociation energies (BDEs) $< 92 \text{ kcal mol}^{-1}$) by the sterically hindered *t*-butoxy radical is entropy controlled [11], the general implication of the Evans–Polanyi relationship is that the rate constants for H-abstraction are expected to increase with decreasing BDE. This suggests that a consideration of BDEs [12] would be a reasonable way to identify suitable H-donors for photochemical H-abstraction (Table 19.1, Column 1), and that there should be a

TABLE 19.1 Correlation between Reactivity of H-Donors and Bond Dissociation Energy (BDE)

H-Donors That Produce Nucleophilic C-Radicals				H-Donors That Produce Non-Nucleophilic C-Radicals		Systems That Are Unsuitable as H-Donors due to Large C-H BDE

^a kJ mol⁻¹; values taken from Ref. [12].

correlation between the regioselectivity of the process and the strength of the various C-H bonds in a molecule. There are however many C-H systems with relatively small BDEs that do not participate in C-C bond formation with electron-deficient alkenes following H-abstraction (Table 19.1, Column 2). The radicals in these cases have, as a result of resonance, low-energy SOMOs, which will not interact with the alkene LUMO, and are thus non-nucleophilic. Interestingly, resonance is also the reason why the abstraction of an aldehydic hydrogen occurs so readily (Table 19.1, Column 1) and why the acyl radicals thus formed are nucleophilic (Figure 19.1). For many molecules, the size of the BDE of their C-H bonds precludes H-abstraction on thermodynamic grounds (Table 19.1, Column 3). In addition to resonance and the general BDE order, primary C-H > secondary C-H > tertiary C-H, which reflects the induction and hyperconjugation determined stability of the C-radicals resulting from the dissociation, a number of other factors have been implicated in the C-H bond dissociation process. The rate of H-abstraction from C-H bonds α to O-atoms (Table 19.1, Column 1), for example, is subject to a stereoelectronic effect [13–16]. A high rate is associated with a small dihedral angle, θ , between the p-type lone pair of electrons on the O-atom and the dissociating C-H bond (Figure 19.2). A similar effect has

**FIGURE 19.1****FIGURE 19.2**

been observed for amines [17], with those for which the α -C-H and the lone pair of the N-atom have an eclipsing relationship again being the most reactive. A strain-enhanced hyperconjugation effect, involving the cyclobutane ring, has been invoked in an attempt to rationalize the surprisingly low BDE of the α -keto methylene hydrogens in pinonaldehyde [18].

The photomediated reaction of alcohols with alkynes [19] provides a good example of what can be expected from photomediated H-abstraction in terms of reactivity and regioselectivity (Table 19.2). The highly regiospecific abstraction of the methine hydrogen in 1,2-propanediol and 1,2-butanediol is an example of the well-established preference for the formation of a tertiary rather than a secondary radical. The difference between the BDEs of the α -C-H bonds of 1-propanol and 2-propanol, 399.5 and 390.5 kJ mol⁻¹ [20], respectively, contributes to the observed regiochemical preference. The essentially exclusive formation of a product derived from the formal cleavage of the methine C-H bond may also be in part due to the fact that a large excess of the alcohol is involved, as is usual in this type of reaction [21], resulting in the conversion of any secondary radicals to the corresponding, and more thermodynamically stable, tertiary radicals. Although the methine C-H in 2-pentanol still enjoys a BDE advantage relative to the other C-H bonds, this is now balanced by the statistical effect of the increased number of C-H bonds and the formation of a complex mixture of addition products ensues. Overall, synthetically useful photochemical H-abstractions involve H-donors of the general types discussed earlier (Table 19.1, Column 1), which for reasons of reactivity and/or symmetry contain effectively only one reactive C-H bond. In practice, and as discussed earlier, the requirement for a large excess of the H-donor generally restricts the process to H-donors of relatively high volatility, which can be removed by distillation once the reaction is complete.

19.1.3 Photomediators

In terms of synthetic applications, benzophenone is the most extensively used photomediator and in many ways is a model of how a good photomediator should behave. It has absorption bands at approximately 350 nm, a wavelength where most of the reactants and products that might be involved in the process are almost transparent and so there is little competition for the incident light. The formation of its triplet state occurs with $\Phi \sim 1$, the (n, π^*) configuration being the lowest in energy. This has a relatively long lifetime (0.71 ms [22]) and involves a significant localization of spin density on the O-atom that gives it the alkoxy radical character, which is essential in terms of H-abstraction. Ketones for which the lowest triplet state is of the (π, π^*) type do not have alkoxy radical character and so do not function as photomediators [23]. The benzophenone ketyl radical, the product of the H-abstraction process, is very stable for electronic and steric reasons and does not interact with either the unsaturated reactant or the product; it does however complete the reaction by back transferring the abstracted H-atom to the product radical (Scheme 19.2). Dimerization of the ketyl radical becomes competitive if this back transfer is slow (Scheme 19.2); as outlined earlier, this removes the photomediator from the reaction loop, necessitating the use of larger amounts in order to secure complete reaction, and thus adding to the problems associated with product isolation. The effectiveness of a photomediator can also be reduced if it undergoes a unimolecular reaction. Thus although the reactivity of decafluorobenzophenone in terms of H-abstraction from alkanes and alcohols is 10–40 times greater than that of benzophenone [24], an effect attributed to enhanced spin localization on the carbonyl oxygen [25], its attractiveness is reduced by a propensity to undergo a disproportionation reaction forming decafluorobenzhydrol in polar solvents [26]. In general however, the effect of substituents on the rate of H-abstraction has been shown to be relatively slight, with a single order of magnitude covering the reactivities of a range of typical aromatic ketones [27]. Thus, for example, acetophenone, and benzophenone have almost identical reactivities.

All these photomediators suffer, however, from the disadvantage that chromatography is required to remove them from the product mixture, an issue that becomes more problematic as the amount of photomediator required to promote the reaction increases. Although less desirable from the photophysical and photochemical perspectives, the use of acetone as photomediator, and often as cosolvent, obviates this problem. The availability of a range of water-soluble derivatives of benzophenone [28], such as the sulfonic

acid sodium salt (**1**) [29] or the commercially available quaternary ammonium salt (**2**) [30], enhances the methodology from the green chemistry perspective. In addition such photomediators can be separated from the reaction product without the need for chromatography. A number of inorganic ions, particularly the decatungstate anion, $W_{10}O_{32}^{4-}$, in the form of the acetonitrile soluble TBADT, have also found use as photomediators [31,32]. TBADT is similar to benzophenone in that it absorbs at approximately 350 nm, but significantly it is reported to be effective in catalytic amounts in systems where a stoichiometric quantity of benzophenone is required, all of which is converted to a variety of by-products in the course of the reaction [33]; in addition their use involves a simpler product isolation procedure than is the case with aromatic ketones. The efficiency of the decatungstate anion, in comparison to that of aromatic ketones, has been attributed to the relative rates of back H-transfer to the radical precursor of the product. The immobilization of photomediators on solid supports offers to these reactions the same advantages that have encouraged the development of supported reagents and catalysts for a wide variety of synthetic applications: ease of removal of the reagent, facilitating its reuse, and the purification of the reaction product. In this context, supported photomediators based on silica, or a Merrifield resin, have been successfully used to promote the reaction of cycloalkanes [8] and secondary alcohols [19] with alkynes. The green credentials of photochemical H-abstraction are further enhanced by the fact that these supported photomediators, and indeed soluble photomediators such as benzophenone and TBADT as well, function under solar conditions [7], the molar spectral direct solar irradiance at sea level being typically $0.8 \text{ mol m}^{-2} \text{ s}^{-1} \text{ nm}^{-1}$ at 350 nm [34].

19.1.4 Unsaturated Systems

The addition of a nucleophilic C-radical to an unsaturated system containing at least one C-atom results in the formation of a C–C bond (Scheme 19.1). The reaction is thus effectively a Michael reaction and is most successful with alkenes and alkynes activated by the presence of one or more of the usual electron-withdrawing groups (EWGs): $-\text{C}(\text{O})\text{R}$, $-\text{CO}_2\text{R}$, $\text{C}(\text{O})\text{H}$, $\text{C}(\text{O})\text{NH}_2$, $-\text{SO}_2\text{R}$, CN , CO_2H , etc. On the other hand, the electronically neutral styrene appears to be unreactive, as the photomediated addition of standard H-donors such as 2-propanol, THF, 2-alkyl-1,3-dioxolanes, aldehydes or cyclohexane, to this alkene has not been reported. Phenylacetylene is more reactive and 1-methyl-1,3-dioxolane [16] and THF [35] have been successfully added to this alkyne (Scheme 19.3).^{*} This limitation on the type of unsaturated component that can be used also applies to thermally generated C-radicals, as the few reported examples of the addition of such radicals to alkenes and alkynes without EWGs involve extreme conditions: sealed tube reactions in a microwave at 200° [36], high temperatures [37], supercritical alcohols at 350° [38], high temperatures and pressures [39], or high temperatures and peroxides [40]. The thiol-catalyzed addition

SCHEME 19.3

^{*} The amount of photomediator used is a key parameter for these and similar reactions. As in almost all cases the H-donor is used in large excess, a sense of the amount of photomediator used is best conveyed in terms of the number of equivalents used relative to the unsaturated system. This method of reporting has been adopted consistently in this review.

SCHEME 19.4

of acyl radicals, generated from aldehydes using *t*-butoxy radicals derived from di-*t*-butyl hyponitrite, to enol acetates, vinyl ethers, etc., is a rare example of a reaction involving electron-rich alkenes [41].

In view of the nucleophilic character of C-radicals, they would be expected to react with the electrophilic carbon of a C=N bond and in accordance with this expectation a range of C–C bond forming reactions involving the interaction of photochemically produced C-radicals with imine and oxime bonds have been reported (see the following). On the other hand, examples of the addition of C-radicals to carbonyl bonds are extremely rare and there does not appear to be any that involve C-radicals produced by photochemical H-abstraction. Although the isolation from photochemical reactions of products such as (3) (Scheme 19.4), formally the result of the addition of an α -hydroxyalkyl radical to a carbonyl group, is common, these actually result from the recombination of two α -hydroxyalkyl radicals [42]. The relative reactivity of C=C, C=N, and C=O bonds in relation to radical addition can be attributed to the strengths of the π -bonds [43], an estimate of which is given by the difference between the average bond energies of the respective single and double bonds: C=C, 270 kJ mol⁻¹; C=N, 295 kJ mol⁻¹; and C=O, 373 kJ mol⁻¹ [44].

19.2 Photochemical Addition Reactions of Cycloalkanes

The photomediated reaction of a cycloalkane with an electron-deficient unsaturated system is of importance as it is one of the relatively few methods of resolving a classic problem of synthetic organic chemistry, the functionalization of an unactivated C–H bond. The first examples of the photochemical addition of a cycloalkane to an unsaturated system were independently reported within 6 months of each other in 1969 [45,46]. Synthetically, they were not encouraging (Scheme 19.5). A photomediator was not used in either case, the reactions presumably involving the abstraction of a hydrogen from cyclohexane by an electronically excited substrate molecule, an ynoate in each case. Recombination within the solvent cage or the addition of the C-radical to another unsaturated molecule accounts for the formation of the observed products. The formation of 3-cyclohexylcyclopentanone in 22% yield on irradiation of a solution of cyclopenten-2-one in cyclohexane is the result of a similar process [47]. The only other example of this type of

SCHEME 19.5

SCHEME 19.6

reaction is more recent and involves the herbicide vinclozolin (**4**), which on irradiation in cyclohexane produces a monochloro cyclohexyl adduct (Scheme 19.6) [48]. Although the precise origin of the cyclohexyl radicals is unclear, the reaction is notable as it is the only example of the addition of a photochemically generated cycloalkyl radical to an alkene that does not have an EWG as a substituent.

The first example of the deliberate use of a photomediator to generate cycloalkyl radicals for subsequent reaction relates to the benzophenone mediated photoreaction of hexafluorobenzene with cyclohexane (Scheme 19.7) [49]; benzpinacol was produced as a by-product. Interestingly, cyclopentane performed poorly in this reaction, giving instead larger amounts of benzpinacol, and also bicyclopentyl. Cycloheptane and a number of *n*-alkanes failed to react. The use of xanthone to promote the addition of cyclohexane, or an alcohol, to an unsaturated thiolactone is another early example of the use of an aromatic ketone as a photomediator (Scheme 19.8) [50]. In the last decade a number of systematic studies have helped to define the synthetic scope of the process in terms of substrate, photomediator, and general reaction conditions (Table 19.3). In many of the reactions reported, dimerization of the photomediator-derived ketyl radical,

^a Photomediator.^b Relative to the unsaturated substrate.

forming a pinacol, is competitive with back transfer of a H-atom to the product forming radical. This has led to a need to use up to 1 eq of photomediator in order to ensure complete reaction of the unsaturated substrate and to consequential problems in terms of product isolation. The use of the silica- and Merrifield resin-supported photomediators, (5) and (6), respectively, facilitates product purification and opens up the potential for facile recovery and recycling of the photomediator [8]. Ketyl radical dimerization, and thus removal of the photomediator from the reaction cycle, should also be less of a problem with these supported photomediators if the surface coverage is kept low. In terms of the photomediator, alkynes appear to be more attractive as substrates in that as little as 0.14 eq of benzophenone can be used without adversely affecting either the yield or the rate of the reaction [5]. Interestingly the rate of the reaction, but not the yield, drops dramatically if the amount of photomediator is reduced below this level. This difference between the behavior of alkenes and alkynes as substrates may relate to the relative reactivity of the respective alkyl and alkenyl radical intermediates in terms of H-transfer. No overall pattern emerges in terms of the relative reactivity of the cycloalkanes. Thus although cyclopentane is the most reactive in terms of the alkynes [5], it is much less reactive than cyclohexane in terms of reaction with hexafluorobenzene [49], and whereas DMAD does not react with cycloalkanes larger than the cyclohexane [6], 2-cyclopentenone reacts readily with dodecane (Table 19.3, Entry 5) [33].

The use of TBADT as a photomediator has also been reported [54], with direct H-abstraction again being the key step in the generation of C-radicals from H-donors such as cycloalkanes [55]. The synthetic potential of this photomediator is considerable in the context, again, of reactions involving electron-deficient alkenes (Table 19.3, Entry 10) [9,56], with the fact that it is effective in catalytic quantities being particularly attractive [33]. The difference between TBADT and aromatic ketones in terms of the rate of the final back H-transfer to the radical precursor of the product, the factor that is believed to be responsible for the activity of the former [31], provides the opportunity of controlling the synthetic outcome of a reaction through an appropriate choice of photomediator (Scheme 19.9) [52,56]. A careful examination of the alkylation of monoalkylcyclohexanes indicates that these reactions deliver a modest level of regio- and stereoselectivity, with similar product distributions being obtained with both benzophenone and TBADT (Scheme 19.10) [31]. The observed selectivity is attributed to steric factors.

Although the addition of thermally generated carbon radicals to C=N bonds is currently an active area of research [57], there appears to be only one report of the addition to C=N bonds of cycloalkyl radicals, which have been generated by photomediated H-transfer. This involves an exploration of the use of polytungstates, including TBADT, in the functionalization of a series of hydrocarbons using methyl cyanoformate (Scheme 19.11) [58]. The data obtained confirm that the key step is a H-atom transfer involving an electronically excited decatungstate ion (Scheme 19.12). This is followed by the establishment of a radical chain in which the key intermediate is the iminyl radical (8). If the reaction is conducted at room temperature, competitive breakdown of this radical to form a nitrile is minimal (1%–2%); at 90° this becomes the predominant process. In addition to underlining the potential of polyoxotungstates as photomediators, this work provides a rare example of the functionalization of an acyclic hydrocarbon and illustrates how non-nucleophilic allylic and benzylic radicals undergo recombination rather than addition to an unsaturated bond.

19.3 Photomediated Addition Reactions of Cyclic Ethers

The photomediated α -alkylation and α -alkenylation of cyclic ethers constitute further examples of the use of this synthetic methodology for the functionalization of an unactivated system more usually viewed as a solvent than as a substrate. The α -alkoxyalkyl radicals resulting from H-abstraction would be expected to be more reactive than the corresponding cycloalkyl radicals due to the stereoelectronic effect involving the p-type lone pair of electrons on the O-atom [13–16]; this is reflected in the existence of a resonance form in which the α -carbon is carbanionic (Figure 19.3). The first systematic study of reactions of this type described the addition of THF, and other cyclic ethers, to diethyl maleate and fumarate

SCHEME 19.9

SCHEME 19.10

(Scheme 19.13) [59], and the formation of pinacols and cyclic ether dimers as by-products. Interestingly however the solar chemistry potential of the process was recognized and indeed product yields obtained using sunlight for a range of cyclic ethers were higher than those obtained using a high-pressure mercury vapor lamp. Although the greater nucleophilic character of the C-radicals produced from THF, relative to cycloalkyl radicals, may play a role in accounting for their reaction with the relatively electron-rich terminal alkene, 1-heptene, the fact that reaction occurs at the less sterically hindered alkene carbon, rather than at the most electrophilic, suggests that steric factors may be decisive, as is so often the case in the reactions being considered here. Other examples of this behavior even include the direct addition of diethyl ether to the terminal alkene unit in (9) (Scheme 19.14) [60], a process that presumably involves the unsaturated lactone acting as the photomediator, but in what may be another example of the importance of steric effects in these reactions, does not result in radical addition to its alkene bond. In the context of the reaction between DMAD, and either THF or oxetane [61], the involvement of a ketone–ether exciplex and of a ether–alkyne charge-transfer complex have been suggested for the ketone-photomediated and direct reactions, respectively. The possibility that the direct addition of THF to an enone involves a SET

Condition: $h\nu > 280$ nm (pyrex), MeCN, 0.006 eq polyoxotungstate, rt, yields based on a methyl cyanocarbonate conversion of approximately 15%

SCHEME 19.13

SCHEME 19.14

mechanism was, however, considered improbable on the basis of the high oxidation potentials of aliphatic ethers in relation to the expected electron affinities of the excited states of the enones [62].

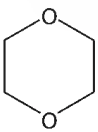

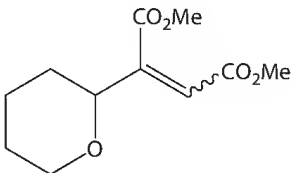

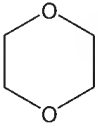

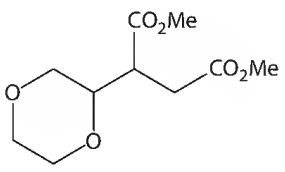

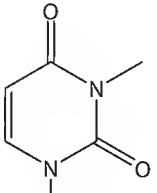

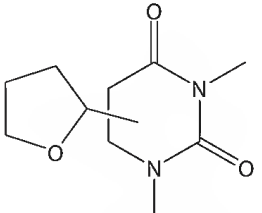

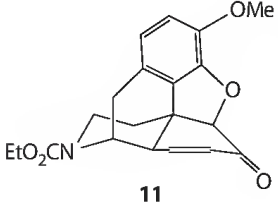

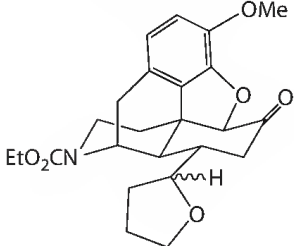

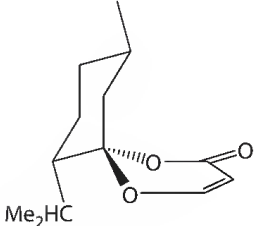

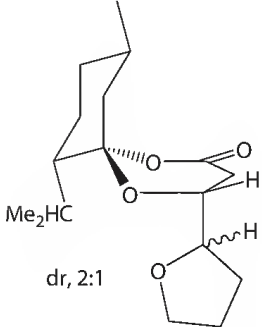

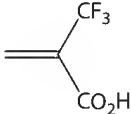

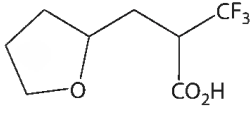

Most of the synthetically interesting examples of the photochemical addition of ethers to carbon–carbon multiple bonds involve cyclic ethers, and electron-deficient alkenes and alkynes (Table 19.4). Many of these reactions (Table 19.4, Entries 3–6) involve direct irradiation. The formation of a regioisomeric mixture on addition of THF to the 1,3-dimethyluracil (**10**) (Table 19.4, Entry 3) is not unprecedented (cf. Scheme 19.8) and is best understood in terms of competitive H-abstraction by the carbonyl group and the β -carbon of the enone [64]. A high degree of stereoselectivity is observed in those reactions where face selectivity is an issue. Thus although the addition of THF to the norcodeinone (**11**) (Table 19.4, Entry 4) generates a mixture of diastereomers as a result of the generation of a new stereogenic center on the THF ring, the product is stereochemically pure at what was the β -carbon of the enone [62]. In the same way, the addition of a THF derived α -alkoxyalkyl radical to the 1,3-dioxin-4-one (**12**) (Table 19.4, Entry 5) occurs stereoselectively on its more exposed face [65]. In terms of the unsaturated system (**12**), the radical's behavior was found to be similar to that observed for a diene in an Diels–Alder reaction or an alkene in a photochemical [2 + 2] cycloaddition, rather than that of a nucleophile in a cuprate addition.

Fluorinated alkenes, or alkenes with a trifluoromethyl substituent, are electron-deficient and react readily with the nucleophilic α -alkoxyalkyl radicals derived from cyclic ethers. If a photochemical approach is employed to generate the radicals, a photomediator is not in general essential (Table 19.4, Entry 6) [66] as irradiation of the fluorinated alkene results in the generation of a triplet state, which because of its biradical character is capable of abstracting an α -H-atom from the ether [67]. In the usual way however, acetone has also been employed as a photomediator in some reactions involving fluorinated alkenes. An order of reactivity has been established for the reaction with fluorinated alkenes of the α -alkoxyalkyl radicals derived from cyclic ethers using γ -radiation: oxolane > oxepane > oxane \approx dioxane [68]. This order is identical to that observed previously by others and rationalized on the basis of a stereoelectronic effect involving the oxygen's p-type lone pair of electrons (Section 19.2) [15].

The diastereoselective addition of the α -alkoxyalkyl radical from THF to the chiral 4-methyleneoxazolidin-5-one (**13**) (Table 19.4, Entry 7) forms the basis of a method for the preparation of chiral homoserine derivatives [69]. The ability of the polytungstate TBADT to act as a photocatalyst is again evident in terms of the addition of ethers to electron-poor alkenes (Table 19.4, Entry 8) [9]. α -Alkoxyalkyl radicals have also been generated using hydroxyl radicals derived photochemically from *N*-hydroxy-2-pyridinethione (**14**) (Scheme 19.15) [71]. The radicals generated in this way add to vinyl sulfone, with the resulting α -sulfonylalkyl radical abstracting a H-atom from a solvent molecule, or undergoing recombination with the thio radical, which is also formed on homolysis of (**14**).

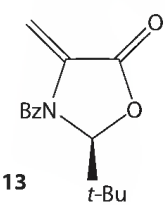

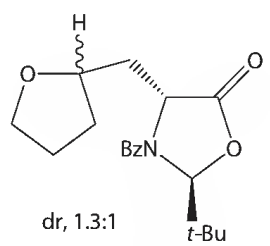

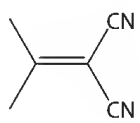

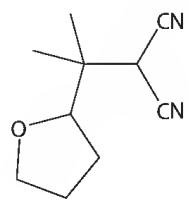

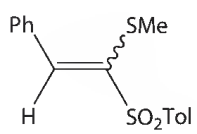

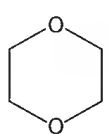

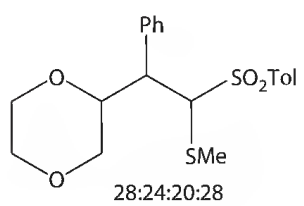

In principle, the addition of an ether to a C=N bond can occur in two ways: a process in which the key step is H-atom transfer, or one that involves a SET. Many involve the latter and thus fall outside the scope of this review. Thus, for example, following a consideration of both mechanisms, it was

SCHEME 19.15

concluded that the addition of THF to iminium salts occurs via a SET pathway [72]. The addition of THF to *N*-phenylimines also occurs by the same route [73]. There are however a number of examples of the addition of photochemically generated α -alkoxyalkyl radicals to C=N bonds that involve a H-atom transfer. The addition of cyclic and acyclic ethers, and uniquely of cyclic (Scheme 19.16) and acyclic thioethers, to pyrimidin-2(1*H*)-ones is believed, for example, to involve H-abstraction by the imino group nitrogen of the pyrimidone in its triplet state [74]. The reaction is thus a formal 1,4-addition to a 1-azadiene. A more conventional example of the photoaddition of an ether to a C=N bond is provided by the acetone-mediated reaction of 1,4-dioxane with the pyrimido[4,5-*d*]pyridazine (15) (Scheme 19.17) [75]. Interestingly, the product appears to have been obtained as a single diastereomer.

SCHEME 19.16

SCHEME 19.17

19.4 Photomediated Addition Reactions of 1,3-Dioxolanes and Related Systems

The 1,3-dioxanyl radical, which is readily accessible through photochemical H-abstraction, is synthetically equivalent to an acyl anion (Scheme 19.18). As the 1,3-dioxolane precursor is readily available from the corresponding aldehyde, and as the H-abstraction occurs under neutral conditions, this method of generating an acyl anion equivalent has found application in multistep syntheses. The stereoelectronic assistance that is available from at least one of the oxygen lone pairs of electrons [13–15] ensures that in terms of H-abstraction, a 1,3-dioxolane is particularly reactive at its 2-position, and that the addition of the resulting 1,3-dioxan-2-yl radical to electron-deficient unsaturated systems is an efficient process. This is particularly true of 2-methyl-1,3-dioxolane whose regiospecific and essentially quantitative reaction with DMAD, for example, is complete in 15 min (Scheme 19.19) [16]. The first reported example of this type of reaction involves the acetone-, acetophenone-, or benzophenone-mediated addition of 1,3-dioxolane and 1,3,5-trioxane to diethyl maleate, and, interestingly, to terminal alkenes (Table 19.5, Entries 1–3) [76]. Dioxolane or trioxane dimers, and photomediator-alkene adducts were obtained as by-products and once again the yields reported for reactions carried out in sunlight were higher than those

SCHEME 19.18

SCHEME 19.19

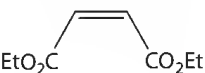

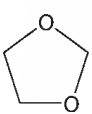

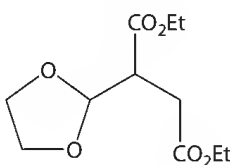

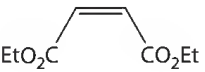

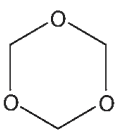

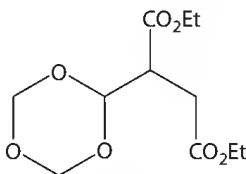

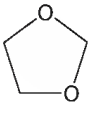

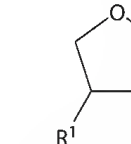

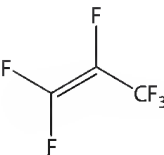

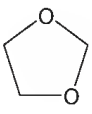

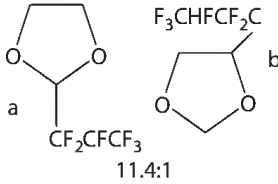

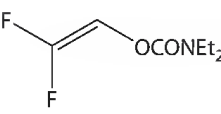

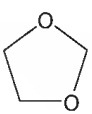

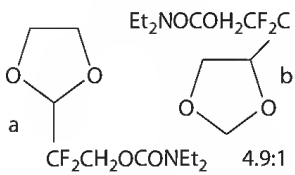

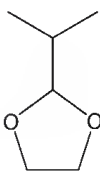

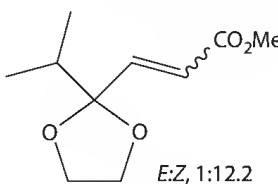

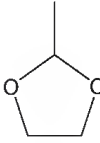

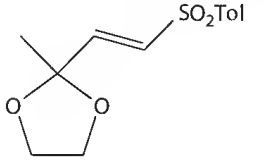

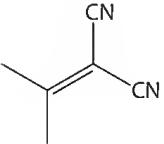

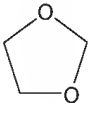

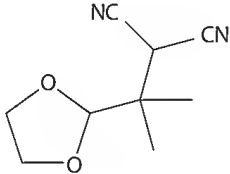

carried out using a mercury vapor lamp. The regioselectivity of the reactions involving terminal alkenes again suggests that steric rather than electronic factors are product determining. The same regioselectivity is observed in the addition of 1,3-dioxolane to the alkene units in the furanoses (**16**) and (**17**) (Scheme 19.20), the reaction of the latter being stereoselective as well [77]. Its photoaddition to enones with endocyclic double bonds also occurs regiospecifically and with a high degree of stereoselectivity [78].

Although the reaction is not completely regioselective, the addition of photochemically generated dioxanyl radicals to fluorinated alkenes occurs readily (Table 19.5, Entry 4) [79]. The regioselectivity of the addition of methylated dioxolanes to perfluoroalkenes has been considered in detail [79], and reaction at both the 2- and the 4-position is also a feature of the addition of 1,3-dioxolane to 2,2-difluorovinyl carbamate (Table 19.5, Entry 5) [80]. On the other hand, the reaction of 1,3-dioxolane, and even of 2-isopropyl-1,3-dioxolane, with a wide range of mono- and di-substituted alkynes is entirely regioselective. The reaction occurs remarkably rapidly and in high yield, the result in the case of the 2-alkylated dioxolanes of a particularly favorable stereoelectronic effect involving the 2-CH bond and the p-type lone pairs of electrons of both O-atoms (Table 19.5, Entry 6, 7) [16]. Regioselectivity is not a problem either in the decatungstate-catalyzed reaction of 1,3-dioxolane with α,β -unsaturated nitriles; very low concentrations of TBADT are again sufficient to promote the alkylation process (Table 19.5, Entry 8) [9].

1,3-Dioxolanes readily undergo a photomediated addition reaction with simple cyclic and acyclic enones [29,81,82], which is synthetically valuable as it provides ready access to monoprotected 1,4-dicarbonyl compounds. If 1,3-dioxolane itself is used, a monoprotected 1,4-ketoaldehyde is obtained (Scheme 19.21) [29]; as subsequent hydrolysis would give a 1,4-ketoaldehyde, the process overall results in the β -formylation of the enone. The reactions can be carried out in neat dioxolane using benzophenone as photomediator, or in water/MeCN/dioxolane mixtures using the water-soluble benzophenone disodium disulfonate. The photochemistry of the initially formed 4-oxobutanal acetals can also be exploited with open-chain systems undergoing a Yang cyclization affording hydroxycyclobutanols, aryl derivatives a Norrish Type II cleavage, and cyclic ketones a Norrish Type I cleavage (Scheme 19.22) [81]. If a 2-alkyl-1,3-dioxolane is used, hydrolysis of the product would give a 1,4-diketone, the reaction constituting a formal β -acylation of the enone (Scheme 19.21) [82]. In the context of this particular application, the thermal generation of dioxanyl radicals using initiators such as AIBN or benzoyl peroxide led to significantly poorer results. A high degree of stereoselectivity is observed in the addition of 2-substituted 1,3-dioxolanes to carbohydrate enones (Scheme 19.23), although surprisingly the steroidal enones, 1-cholesten-3-one and 1-cholesten-3-one, fail to react [83,84]. It is worth noting that although these enones are equally unreactive in terms of the addition of alcohols, the photomediated addition of aldehydes occurs in modest yield (Section 19.5). The photomediated reaction of 1,3-dioxolane to the electronically related 3-nitro-2-enopyranosides also produces adducts but with varying levels of stereoselectivity [85].

There is also an increasing number of applications that demonstrate the potential for stereochemical control in the addition of photochemically generated 1,3-dioxolanyl radicals to unsaturated systems in general. The addition of these radicals to (*E*)-fumaryl-bis(oxazolidines), for example, occurs with a de of between 88.9% and 98.9% (Scheme 19.24) [86], and the photoadduct resulting from the addition of 1,3-dioxolane to the chiral 4-methyleneoxazolidin-5-ones (**13**) (Scheme 19.24) [69] is formed with a de of >98%. The addition of dioxolane to chiral cyclic and acyclic α -(arylsulfinyl)enones is

SCHEME 19.21

SCHEME 19.22

SCHEME 19.23

SCHEME 19.24

SCHEME 19.25

a further example of the stereochemical potential of these photomediated reactions (Scheme 19.25) [87]. The 1,3-asymmetric induction achieved in these reactions is due to a face selectivity that is the result of a steric interaction between the bulky arylsulfinyl groups and the incoming radical. The sulfinyl group can be removed and thus the reaction sequence constitutes a method of synthesizing chiral 3-substituted 1-cyclopentanones and 4-substituted 2 pentanones.

Cyclization procedures based on the intramolecular additions of 1,3-dioxanyl and related radicals have been reported with stereoselectivity again being a feature of the reactions in many cases. Thus the irradiation of a benzene solution of the 1,3-dithiane (**18**), containing benzophenone, gave the cyclized product (**19**) (Scheme 19.26) [88]. A detailed analysis of this photocyclization indicated that although the corresponding 1,3-dithiolane was equally reactive, the corresponding 1,3-oxathiane and 1,3-dioxolane were significantly less so. The presence of an EWG on the alkene was essential and the reaction failed with tethered alkynes; attempts to produce seven-membered rings also failed. Chiral acetals, such as (**20**), produced separable mixtures of diastereomers. A similar photomediated cyclization of the dioxecines (**21**) gives the doubly spiro products (**22**) (Scheme 19.27) [65]; cyclization of chiral dioxecines related to (**12**) occurs with very low levels of diastereoselectivity. Synthetic studies related to the synthesis of (–)-tetrodotoxin have included the development of a tandem radical addition–cyclization of procedure based on alkynyl ketoxime ethers (Scheme 19.28) [89]. Radical addition to the alkyne

SCHEME 19.26

SCHEME 19.27

SCHEME 19.28

generates an alkenyl radical that adds to the $\text{C}=\text{N}$ of the oxime ether to give a cyclized product. It was found that the regioselectivity of the radical addition to the alkyne was dependent on the alkyne substituent and the radical involved, creating the possibility of controlling whether cyclization resulted in the formation of a six- or a five-membered ring. 1,3-Dioxanyl radicals, produced by photomediated H-abstraction, gave selectively the former.

SCHEME 19.29

Relatively few examples of the addition of dioxanyl radicals to C=N bonds have been reported. Their intermolecular addition to ketoxime ethers leads to the formation of α,α -disubstituted amino acid derivatives (**23**) (Scheme 19.29), a reaction that, with appropriate substrates, occurs with complete diastereoselectivity [90]. Photoaddition to *N*-acyl aldohydrazones derived from 3-amino-4-benzyl-1,3-oxazolan-2-one (**24**) (Scheme 19.29) proceed with reasonable diastereoselectivity, particularly in the presence of InCl_3 , and so the approach constitutes a method for the preparation of enantiomerically pure α -amino acids [91].

The photomediated addition of 1,3-dioxolanes has been used as the key step in a number of synthetic methodologies and target syntheses. The addition of 1,3-dioxolane to α -cyanovinylsulfones, for example, occurs in good to excellent yield and the 3-cyano-3-sulfonylpropanal acetals thus formed can be converted to 3,4-disubstituted pyrroles [92]. The first step in the total synthesis of the pancreatic lipase inhibitor, (–)-tetrahydrolipstatin (**25**) involves the acetophenone-mediated addition of 2-undecyl-1,3-dioxolane to the exocyclic double bond of diketene (Scheme 19.30) [93]. Similarly, the highly diastereoselective addition of 1,3-dioxolane to the unsaturated γ -lactone (**26**) is a key step in the synthesis of a bis-tetrahydrofuran ligand for a HIV protease inhibitor (**27**) (Scheme 19.31) [94].

19.5 Photomediated Addition Reactions of Aldehydes and Related Systems

The photoacylation of an alkene can be achieved, as indicated in the previous section, by the photomediated addition of 1,3-dioxolane, or 2-alkylated-1,3-dioxolanes, and the subsequent hydrolysis of the dioxolane ring. The photoacylation of an alkene can also be carried out by the direct addition of an aldehyde. Apart from its scientific value, this process is of enormous historical importance for organic photochemistry as the photoacylation of quinones, a classic example of the type of reaction being considered here, was discovered by Klinger in 1888 [95] and was thus one of the very first organic photochemical reactions to be identified and studied. The importance of photoacylation as it applies to simple alkenes is similar, as this process was first described in one of Kharasch's seminal papers on radical chemistry, which appeared in the 1940s [96]. This report related to the photochemical and peroxide-promoted addition of aldehydes to terminal alkenes, with the best results being obtained in reactions involving long-chain aldehydes and long-chain alkenes (Table 19.6, Entry 1). Combinations involving styrene or butenal underwent

SCHEME 19.30

SCHEME 19.31

polymerization exclusively, and cyclohexene gave very poor yields of adducts. It was also noted that reactions that were initiated photochemically gave less complex mixtures than those obtained from reactions involving acyl peroxides. Another early contribution in this area reported that irradiation of a mixture of propionaldehyde and cyclohexene resulted in the competitive formation of a photoacylation product and an unsaturated alcohol produced by the recombination of cyclohexenyl and ketyl radicals (Table 19.6, Entry 2) [97].

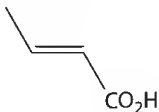

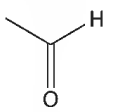

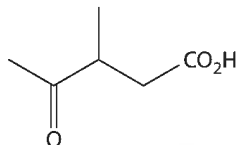

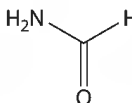

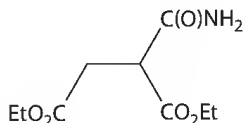

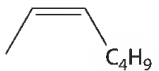

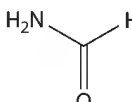

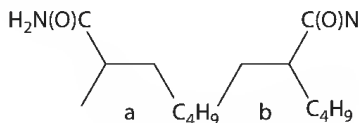

There are very few reports relating to the photochemical addition of aldehydes to alkynes, the earliest of which again features an unactivated system (Scheme 19.32) [98]. Although the reaction produces small amounts of a variety of radical recombination products, it is worth noting that (**28**), (**29**), and (**30**), the products of the photoacylation of 1-hexyne and subsequently of the enone thus formed, are obtained in a combined yield of 80%. Early results with electron-deficient fluoroalkenes were disappointing from

SCHEME 19.32

the synthetic perspective as gas-phase reactions involving acetaldehyde gave not only the ketone resulting from photoacylation, but in some cases the oxetane formed by the [2 + 2] cycloaddition of the aldehyde and the alkene as well (Table 19.6, Entry 3) [99]. The direct photoaddition of pentanal to diethyl maleate, with a quantum yield of about 200, has been achieved using a Nd-YAG pulsed laser as a light source [100]. It is proposed that the key H-abstraction step involves an interaction between ground-state and excited-state aldehyde molecules, a process that must be common to all direct photoacylation reactions. It is suggested that the very large quantum yield is due to the operation of a chain reaction based on a product forming back H-transfer, which involves a molecule of ground-state aldehyde rather than a ketyl radical. The development of a classic tandem intermolecular photoacylation–cyclization procedure with the dienolate (**31**) (Scheme 19.33) provided a basis for comparing a number of different C-radical generation methods [101]. Both photochemical methods were superior to the use of benzoyl

SCHEME 19.33

peroxide; the lower yield obtained with benzophenone, relative to that obtained with the perester, was ascribed to quenching effects that reduce the former's efficiency.

The photomediated addition of aldehydes to enones has been shown to be a general reaction of aliphatic and aromatic aldehydes (Table 19.6, Entry 4) [102], with the addition to carbohydrate enones demonstrating the same, presumably steric driven, stereoselectivity as is observed in the addition of 1,3-dioxanyl radicals (Scheme 19.23) [83,84]. Steric control of stereoselectivity is also a feature of the addition of acyl radicals to 4-cholesten-3-one; the success of this reaction is in contrast to the fact that alcohols and dioxolanes fail to react [84]. The decatungstate TBADT has been shown to possess significant advantages as a photomediator in this area, compared to benzophenone [6]. In catalytic quantities (2 mol%), it effectively promotes the reaction of equimolar mixtures of aliphatic aldehydes and electron-deficient alkenes (Table 19.6, Entry 5). This result is not only important in the context of photomediated intermolecular H-abstraction, but also in terms of almost all thermal and photochemical methods that involve the generation and intermolecular trapping of C-radicals, as the use of a very large excess of the H-donor is a standard feature of such reactions [103]. The fact that the method is photochemical in nature also allows the use of low temperatures to suppress the decarbonylation process, which is competitive with acylation for α -substituted aldehydes (Scheme 19.34) [6]. The photoacylation of [60]-fullerene has also been achieved using TBADT as a photomediator (Table 19.6, Entry 6) [104]. It is believed that the reaction proceeds in the usual way through the addition to the fullerene of acyl radicals generated by H-abstraction from the aldehyde. As in the previous example, a low reaction temperature is used to suppress the decarbonylation of the acyl radicals and

SCHEME 19.34

the consequent formation of alkylfullerenes. This photomediated approach provides access to a wide variety of new C_{60} -based materials.

The photochemical addition of aldehydes to quinones, sometimes referred to as a photo-Friedel–Crafts reaction, has been the topic of systematic research from both synthetic and mechanistic perspectives since it was first discovered in 1888 [95]. The reaction has however been the subject of a thorough and comprehensive review in a previous volume of this work [105] and so will not be considered here. The direct reaction follows the predictable route: H-abstraction from the aldehyde by a triplet state quinone, followed by in cage recombination of the radicals thus formed. Reports that have appeared since the 2004 review provide an indication of the scope of this reaction. One of these focuses on the photoacylation of 2-methyl- and 2-methoxy-1,4-naphthoquinone by direct irradiation (Scheme 19.35) [106]. This process has synthetic value as it results in the formation of a 2,3-disubstituted 1,4-naphthoquinone, a starting point for the synthesis of a range of biologically active quinonoids, which includes antimalarials, antibiotics, and pesticides. Thus the irradiation of a benzene solution of 2-methyl-1,4-naphthoquinone containing an excess of an aldehyde results in the formation of an acylated product (Scheme 19.35), occasionally accompanied by a triketone, which is the result of in-cage radical recombination at the tertiary position. In addition to the acylated quinone, photoacylation of 2-methoxy-1,4-naphthoquinone can also lead to the formation of the corresponding hydroquinone, which is relatively stable in solution but rapidly oxidizes to the quinone in the solid state. A subsequent communication reported an improved procedure for converting 1,4-naphthoquinones to the corresponding 2-acylhydroquinones [107]. This involves the expedient of combining UV lamps with $\lambda_{\text{max}} = 300 \pm 25$ nm with pyrex reaction vessels in an annular reactor. Due of the spectral characteristics of the reactant and product, this results in efficient light absorption by naphthoquinone, with little competition from the product hydroquinone.

SCHEME 19.35

SCHEME 19.36

There appears to be only one example of the photoaddition of an aldehyde to a C=N bond: the direct addition of ethanal, propanal, and butanal gives 8-acyl-8,9-dihydrocaffeines and 8-(α -hydroxyalkyl)caffeines as the major products (Table 19.6, Entry 7) [108], together with smaller amounts of 8,8'-(8-acyl-8,9-dihydrocaffeine) dimers, and 8-acylcaffeines.

A number of synthetic procedures have been developed in which the photoacylation of an alkene plays a key role. Thus the photomediated addition of an aldehyde to α,β -unsaturated esters and acids has been used to produce 4-oxoalkanoic esters and acids in a single step (Table 19.6, Entry 8) [109]. These are synthetically useful building blocks, normally produced from acetoacetates and chloroacetates in a three-step process. A partial synthetic route to sesquiterpene lactones containing an oxetane ring, a structural unit associated with a wide range of biological activity, has been developed in which a key step is the photoaddition of an aldehyde to an α -methylene- γ -lactone (Scheme 19.36) [110]. The development of this synthetic method involved a detailed exploration of the scope and mechanism of the photoacylation process [111,112]. Results were obtained that appeared to suggest that the presence of molecular oxygen promoted the reaction, an effect that was attributed to enhanced intersystem crossing for the aldehyde in the excited singlet state. Overall the picture presented is rather puzzling and it may be worth noting that in the most recent report of the use of the method, no mention is made of a need for molecular oxygen [110]. Ketene dithioacetal S,S-dioxides have been shown to be synthetically versatile components in photoacylation reactions. Thus the adducts obtained from the addition of aromatic aldehydes to (34), in the presence or absence of benzophenone, can be used in the synthesis of indanones (Scheme 19.37) [113]. Efficient 1,2-asymmetric induction is possible if the photoacylation involves 3-hydroxy-1-(methylthio)-1-(*p*-tolylsulfonyl)-1-alkenes or the corresponding acetates [114], an example being the benzophenone-promoted addition of propanal to (35), followed by treatment with Raney nickel, that gave the sulfone (36) as an 83:17 mixture of diastereomers (Scheme 19.38). Finally, an intramolecular photoacylation involving the 3-(3-formylpropyl)furan-2(5*H*)-one (37) (Scheme 19.39) provides a nice example of how varying the photochemical conditions can control the outcome of a reaction [115]. In the presence of benzophenone, the photochemically active species is the benzophenone triplet, which abstracts a H-atom from the aldehyde forming an acyl radical that adds to the enone giving a single bicyclic adduct, (38). In the absence of benzophenone, the photochemically active species

SCHEME 19.37

SCHEME 19.38

is the furanone triplet, which produces an acyl radical by intramolecular H-abstraction. This acyl radical cyclizes to give the spirobicyclic lactones, (**39**) and (**40**).

Photoamidation with formamide is also a general reaction of alkenes, occurring not only for electron-deficient alkenes (Table 19.6, Entry 9) [116,117], but also for unactivated terminal, non-terminal, and cyclic alkenes. Reactions with terminal alkenes occur almost regiospecifically in an anti-Markovnikov sense [118], whereas those with nonterminal alkenes give mixtures (Table 19.6, Entry 10) [119]. The yield obtained in these reactions using solar radiation was in many cases better than that obtained using pyrex-filtered high-pressure mercury lamps [117,119]. The photoamidation of norbornene, directly or in the presence of acetone, gives the *exo* addition product stereoselectively [120]. The acetone- or benzophenone-photomediated amidation of unactivated alkynes has also been reported [121], with surprisingly the major product obtained with a terminal alkyne such as 1-hexyne being (**41**), a 2:2 adduct for which an *E* stereochemistry is assumed. Internal alkynes give preferentially a 1:2 adduct, for example (**42**) in the case of 4-octyne. In terms of synthetic applications with more complex molecules, the stereoselective photomediated α-addition of formamide to the galactal (**43**) is a key step in the synthesis of a daucic acid ester with a *D*-xylo configuration (**44**) (Scheme 19.40) [122]. The synthesis of alkyl-substituted azetidine-2,4-diones has been achieved by the photocyclization of α,β-unsaturated *N*-formyl-*N*-methyl amides (Scheme 19.41) [123]. The reaction is believed to proceed via the 1,4-biradical formed through intramolecular H-abstraction by the electronically excited enone unit.

19.6 Photomediated Addition Reactions of Alcohols

The photochemical addition of secondary and primary alcohols to unsaturated systems extends the synthetic utility of the alcohol functional group in that it opens a reactivity channel, based on the nucleophilic character of the α -hydroxyalkyl radical, which is quite distinct from that which involves the nucleophilic oxygen. The p-type nonbonding electron pair, which is implicated in the weakness of the α -CH bond, is also responsible for the nucleophilic character of the α -hydroxyalkyl radical, a property that is apparent from a consideration of its resonance forms (Figure 19.4). The greater reactivity of secondary alcohols and the failure of benzyl alcohols to react can be attributed to inductive and resonance effects, respectively, in the α -hydroxyalkyl radicals derived from them. The first reported example of the photochemically induced addition of an alcohol to an alkene involved unactivated terminal alkenes under direct conditions and gave telomeric by-products (Table 19.7, Entry 1) [124]. Schenk's synthesis of terebic acid (45) (Scheme 19.42) [125] a few years later demonstrated that the photomediated addition of alcohols had synthetic potential. Another early example involved the irradiation of a solution of pregnadienolone acetate in cyclohexanol giving an addition product, together with the product of a reduction reaction (Table 19.7, Entry 2) [126], a process that has been found to be competitive with addition in other systems as well [127]. Interestingly, the reaction extends to alkenes, which, at least formally, are electron rich (Table 19.7, Entry 4) [129], and in terms of the alcohol component to diols in a reaction that is stereoselective (Table 19.7, Entry 5) [130]. The central role played by photochemical H-abstraction in these processes has been confirmed by a mechanistic study of the benzophenone-mediated addition of methanol to carbohydrate enones [131].

As is the case with all the other H-donors discussed in this review, the photomediated and direct addition of alcohols to the strongly electrophilic double bond in fluoroalkenes have both been extensively used in the synthesis of fluorinated molecules (Table 19.7, Entry 7) [80,132–137]. The addition of secondary alcohols to maleimide has been described (Table 19.7, Entry 8) [138], with this report being among those that note the lower reactivity of primary alcohols [19] and the effective failure of benzyl alcohols to react at all [124]. The psoralens (furocoumarins) give rise to a number of photobiological effects that are due to their photochemical reactions with the pyrimidine bases in DNA that usually involve the formation of [2 + 2] adducts. There are indications that the photocarcinogenicity of the psoralens may also be due to reactions involving the purine bases and model studies suggest that an alcohol photoaddition may be involved. Thus the reaction of the coumarin (46), a psoralen model, with adenosine leads to the formation of the adduct (47) (Scheme 19.43) [139]. Interestingly, other studies

SCHEME 19.43

suggest that a photoreaction involving H-abstraction from the furan ring in adenosine may occur competitively [140]. The irradiation of pyridazine (48) (Scheme 19.44) in the presence of a large excess of an alcohol led to the formation of addition products, which on heating dehydrated and re-aromatized [141]. The reaction of (48) with benzyl alcohol gave (49), a product produced, it is suggested, by a reverse-aldol-type reaction involving an intermediate presumably formed by a H-abstraction-radical recombination sequence (Scheme 19.44). It is worth noting that the potential of TBADT as a photomediator in catalytic quantities has also been demonstrated in terms of the generation of α -hydroxyalkyl radicals (Table 19.7, Entry 9) [9].

The first reported example of the photoaddition of an alcohol to an alkyne involved the direct irradiation of a solution of ethyl propiolate in ethanol or 2-propanol (Scheme 19.45) [45]; the lactone (50) results from the cyclization of the initially formed Z-adduct. Other work, also based on a direct irradiation approach, has indicated that 2-propanol reacts with unactivated monosubstituted alkynes, but not with phenylacetylene, or disubstituted alkynes where the substituents are not activating [142,143]. In contrast, the photoaddition of 2-propanol to phenyl-*t*-butylacetylene, albeit in low yield has been reported [144]. The use of a photomediator dramatically increases the rate and overall yield of reactions involving acetylenes (Table 19.7, Entry 10) [19] and this approach has been applied to a wide range of alkyne/alcohol combinations, which in the case of the latter includes secondary and primary alcohols, and diols

SCHEME 19.44

SCHEME 19.45

SCHEME 19.46

(Scheme 19.46). The formation in these reactions of a γ -butenolide, a common structural unit in many natural products, through the spontaneous cyclization of the initially formed *cis*-3-(hydroxyalkyl) propenoate, is of particular synthetic importance. The synthetically less interesting *trans*-isomer can be converted to the butenolide using NBS, and in the case of (**51**), which is formed stereoselectively from ethylene glycol, the regiochemistry of the cyclization process can be controlled (Scheme 19.46). The effectiveness of supported photomediators particularly those based on silica, which can be removed from the reaction product by simple filtration and are recyclable, further enhances the synthetic potential of this photoaddition reaction [19].

Primary and secondary alcohols have been added, under both direct and photomediated conditions, to a variety of *N*-heterocyclic systems, in what constitutes their addition to an imine bond (Scheme 19.47)

SCHEME 19.47

[75,145–148]. Under direct conditions the reaction involves H-abstraction by the electronically excited heterocyclic system, followed by recombination at the α -position. The photomediated variation involves the normal H-abstraction by the photomediator to give an α -hydroxyalkyl radical, which then adds to the heterocyclic system. The apparently photomediated addition of benzyl alcohol to (52) (Scheme 19.47) [75] is best understood in terms of H-abstraction by the excited heterocyclic system, rather than the nominal photomediator, followed by radical recombination. Depending on the details of the reaction system involved, this may involve either photosensitization or selective excitation of the heterocyclic system. In general, both electronic and stereochemical factors seem to be important in determining the regiochemical outcome of these reactions of *N*-heterocyclic systems.

In common with many of the reactions already discussed, the photoaddition of alcohols to unsaturated systems can occur with varying levels of stereoselectivity. Thus the addition of α -hydroxyalkyl radicals to chiral α -(triisopropylphenyl)sulfinyl enones occurs with the same high levels of diastereoselectivity that were obtained for the addition of dioxanyl radicals (Scheme 19.25) [87]. In a similar fashion the addition of benzophenone produced α -hydroxyalkyl radicals to (*E*)- γ -hydroxy- α,β -unsaturated esters occurred with high *anti*-selectivity, giving selectively the lactone (53) (Scheme 19.48) [149] on cyclization. Radical addition to the acetates of these α,β -unsaturated esters, and the corresponding sulfones, also proceeds with high stereoselectivity, the (*E*)- and (*Z*)-sulfones giving products of opposite stereochemistry. The addition of α -hydroxyalkyl radicals to 3-hydroxy-1-(methylthio)-1-(*p*-tolylsulfonyl)-1-alkenes, again reflecting the outcome of analogous photoacylation reactions (Scheme 19.38) [114], results in high 1,2-asymmetric induction [150,151]. As (35) and analogous alkenes are readily available in chiral form, the method can be used for enantioselective

SCHEME 19.48

syntheses. Chiral induction has also been observed in the photomediated addition of alcohols to the mono- and dimethyl esters of maleic and fumaric acids [152].

Reactions involving the photomediated abstraction of an α -H from an alcohol and the addition of the resulting radical to an unsaturated bond have been used in target synthesis and as subunits in methodologies designed to achieve specific synthetic goals. The photochemical conjugate addition of 2-propanol to carbohydrate derived enones forms part of a procedure that produces cyclohexanes and cyclopentanes from carbohydrates [153] (Scheme 19.49). The approach is based on the earlier work of Fraser-Reid [131,154] and involves using a pendant alkene to trap the intermediate α -keto radical before back H-transfer can occur. The acetophenone-photomediated stereoselective addition of 2-propanol to (S)-5-hydroxymethylfuran-2(5H)-one gave a *trans* 4,5-disubstituted lactone (54), which was used to prepare 3'-C-branched 2',3'-dideoxynucleosides (Scheme 19.50) [155]. In terms of total synthesis, the lactone (54), prepared in this case by direct irradiation in up to 94% yield on a multigram scale, has been converted into (55) an intermediate in the synthesis of the pyrethrin insecticide, *cis*-chrysanthemic acid (56) (Scheme 19.50) [156]. The photoinduced addition of an alcohol to an imine bond has been used to produce an intermediate in the synthesis of the immunosuppressant (+)-myriocin (Scheme 19.51) [90]. Finally, returning to the material that was the subject of one of the earliest publications in this area [125], the asymmetric synthesis of terebic acid has now been carried out using the highly diastereoselective addition of photochemically produced α -hydroxyalkyl radicals to (R)-(-)-menthyloxy-2[5H]-furanone (Scheme 19.52) [157].

19.7 Conclusion

The generation of nucleophilic C-radicals by the intermolecular photomediated abstraction of H-atoms from a donor molecule with a weak C–H bond has considerable synthetic potential. The *in situ* addition of these radicals to unsaturated systems, containing at least one C-atom is, for example, an attractive method of forming C–C bonds, not least because it avoids the use of problematic tin and azo compounds, and peroxides. Other attractions of the approach include the fact that it allows unactivated molecules, such as cyclic ethers and cycloalkanes, to be used as reactants, and further that it opens up reaction pathways for molecules, such as secondary alcohols, which complement their normal mode of reaction. Similarly, direct photoacylation using aldehydes, or indirect using 1,3-dioxolanes, constitutes a synthetically valuable method of introducing a key functional group under mild, neutral conditions. In many cases reactions involving photochemically generated C-radicals occur with high levels of sterically controlled stereoselectivity.

It does have weaknesses, among them the need for a large excess of H-donor, which effectively restricts the methodology to donors that are sufficiently volatile to be removed by distillation following the reaction; the use of small, simple H-donors is also essential because of the lack of selectivity in terms of H-abstraction. The problems associated with the removal of the photomediator also make this approach to C–C bond formation less appealing. In the recent past however there have been developments that have addressed many of these issues. Thus the introduction of TBADT as a photomediator, which is effective in catalytic quantities and, at least in some cases, with approximately equimolar amounts of the unsaturated system and the H-donor, together with the development of supported and water-soluble photomediators, have enhanced the attractiveness of the approach, particularly from the clean/green chemistry perspective. A recent publication [158] touches on many of these issues and focuses on what is an ever interesting, and by no means the least important, aspect of these reactions, the fact that they can be driven by solar radiation.

20.1 Introduction

Photocycloaddition of alkenes to aromatic rings is an important method for chemical conversion and construction of polycyclic compounds. In comparison with photocycloaddition of two alkenes and that of enone with alkenes, mild and chemoselective excitation by light is possible because aromatic rings often have absorption bands in longer wavelengths. In addition, most of them proceed via structurally controlled exciplexes consisting of aromatic rings with alkenes.¹ Therefore, highly selective photocycloaddition can be designed by control of structure and reactivity of substrates and exciplexes, although there are several modes in photocycloaddition of aromatic rings with alkenes, these are [2 + 2], [3 + 2], [4 + 2], [4 + 4], and so on.

The reaction modes are summarized in Scheme 20.1. Photoreaction of benzene and its derivatives proceeds [2 + 2] (*ortho*) and [3 + 2] (*meta*) modes. Arenes and alkenes having either electron-releasing or electron-withdrawing substituents favor the *ortho* addition, whereas relatively simple arenes and alkenes undergo *meta* addition.²⁻⁵ The [4 + 2] (*para*) mode is a rare case. Photocycloaddition to fused aromatic rings occurs onto the positions that have highly double bond character. Namely, 1,2-, 9,10-, 4,5-, and 5,6-positions of naphthalene, phenanthrene, pyrene, and chrysene tend to undergo [2 + 2] photocycloaddition, respectively. Crossed photocycloaddition of alkenes to anthracene hardly proceeds, because [4 + 4] photodimerization of anthracene is a fast and efficient process.

Photocycloaddition of unsaturated bonds such as alkenes, alkynes, and cyclopropanes to aromatic rings is reviewed in this chapter. Since several excellent reviews have been published,⁶⁻¹¹ and previous version of this handbook¹² also treated this topics, recent advances in this field after 2004 will be surveyed.

SCHEME 20.1

20.2 Photocycloaddition of Alkenes to Benzene Derivatives

From a pioneering work by Wender in 1981, that is, synthesis of (\pm)- α -cedrene from compound **1** (Scheme 20.2),¹³ intramolecular *meta*-photocycloaddition between benzene ring and alkenes has been utilized as a key step for the construction of various natural products. Since exhaustive reviews have been published,^{11,14} only recent two examples will be introduced in this section.

Mulzer et al. reported total synthesis of sesquiterpenoids named penifulvins A, B, and C, insecticides with a dioxafenestrane, by means of *meta*-photocycloaddition of enantiomerically pure silphenenes **2a–c**

SCHEME 20.2

SCHEME 20.3

as a key step (Scheme 20.3).^{15,16} The intramolecular *meta*-photocycloaddition of **2a** gave regioisomers **3a** and **4a** in 55:45 ratio. Intramolecular *meta*-photocycloaddition of **2b-c** gave not only **3b-c** and **4b-c** but also epimers at stereogenic centers attaching substituents R^1 and R^2 . The all regioisomers could be separated by flash column chromatography. From the isolated desired isomers **3a-c**, synthesis of enantiomerically pure penifulvins A, B, and C is accomplished.

Chen et al. reported core skeleton of lancifodilactone F, one of the triterpenoid isolated from the Chinese herb *Schisandra*, could be constructed via intramolecular *meta*-photocycloaddition (Scheme 20.4).¹⁷ Photoreaction of racemic **5** produced photocycloadducts **6** and **7** in a 1:1.2 ratio. Since separation of **6** and **7** failed, the mixture was converted to allylic alcohols **8** and **9** by acid hydrolysis after epoxidation. Compounds **8** and **9** could be separated by silica gel column chromatography. A five-step synthesis from **9** afforded compound **10** (racemic), which has a 5,6,7-tricyclic skeleton of lancifodilactone F.

As can be seen in the aforementioned reactions, the intramolecular *meta*-photocycloaddition gives products involving 1,3-addition-2,4-closure, 1,3-addition-2,6-closure, and 2,6-addition-1,3-closure, whose ratio can be controlled by electronic and steric nature of the aromatic rings, alkenes, and tethers (Scheme 20.5).¹⁰

Jenkins et al. reported that photoreaction of diastereomerically pure compound **11**, which has alkyl and hydroxy groups at appropriate positions, gave only 2,6-addition-1,3-closure product **12** as a single diastereomer although there are two possibilities of face selectivity (Scheme 20.6).¹⁸ Sugimura found that asymmetric synthesis of photocycloadducts can be achieved in photoreaction of enantiomerically pure **13** (2*R*, 4*R*) to give **14** and **15** in 40% and 15% yields, respectively.^{19,20} This photoreaction is highly stereocontrolled with the initial addition at the *Si*-face of the vinyl moiety.

SCHEME 20.4

SCHEME 20.5

SCHEME 20.6

SCHEME 20.7

The use of temporary tethers in the *meta*-photocycloaddition was investigated by Penkett et al. in 2004.²¹ Photoreaction of compounds **16a–b** tethered by methylene acetal proceeds regioselectively to give **17a–b** (Scheme 20.7). Epoxidation of **17a–b** followed by treatment with acids gave open-chained allyl alcohols **19a–b**. Disiloxane-tethered compound **20** also undergo regioselective photocycloaddition to give **23** via **21** and **22**. Silyl tethers are known to be also used in control of photodimerization of styrene and stilbene derivatives.^{22–24}

Penkett also reported that when methoxy-substituted benzaldehyde diallyl acetal **24** was irradiated, novel double [3 + 2] photocycloadduct **26** was obtained stereoselectively with the formation of angular triquinanes **27** and **28** (Scheme 20.8).²⁵ When **24** was irradiated to the point of its total consumption, linear triquinane **25** could be detected. From the results of control experiments including the photoreaction of a deuterium-labeled compound, linear triquinane **25** produces **26**, while **27** photoisomerizes to **28**. The fact that photoirradiation of **25** also gave **28** can be explained by photoisomerization between **25** and **27** via a biradical **29**.

SCHEME 20.8

SCHEME 20.9

Yoshimi and Hatanaka reported that sodium salts of *para*-substituted benzoic acids **30a–c** undergo photocycloaddition when it was irradiated in H_2O in the presence of allyl alcohol **31** to give cyclooctatriene derivatives **32a–c** and bicyclooctadienes **33a–b** (Scheme 20.9).²⁶ From the structure of products and the fact that the photoirradiation of the isolated **32b** gave **33b** and *p*-methylbenzoic acid, they concluded that **32** should be produced via [2 + 2] (*ortho*) photocycloadduct **34** but it is reversible, and that **33** produces by the photochemical ring closure of **32**.

Oshima et al. reported when 1,1-diphenylethene **35** was photoirradiated in the presence of methyl-substituted 1,4-benzoquinones **36a–d**, the products, **37** and **38** further reacted intramolecularly to give [2 + 2] (*ortho*) photocycloadducts **39** and **40** reversibly (Scheme 20.10).²⁷

SCHEME 20.10

20.3 Photocycloaddition of Alkenes to Naphthalene Derivatives and Related Arenes

Most of photocycloaddition of alkenes to naphthalene derivatives proceeds at 1,2-position of the naphthalene ring. Kubo et al. has been disclosed unusual [3 + 2] photocycloaddition of alkenes to 1,8-position in 1992.^{28,29} In this section, recent advances in this field are surveyed.

Mizuno et al. have disclosed that the photoirradiation of benzene and acetonitrile solutions containing 2-(2-alkenyloxymethyl)naphthalene-1-carbonitriles **41a–c** afforded photocycloadducts at 1,2-position (**42a–c**) and 2,4-position (**43a–c**) of the naphthalene ring via singlet exciplexes **44** and **45** (Scheme 20.11).^{30,31} The compound **42** was predominantly obtained at the initial stage of the reaction, but prolonged irradiation afforded the [3 + 2] photocycloadduct **43** as a major product, because photocycloreversion from **42** to **41** takes place, but that from **43** to **41** does not occur. This reversibility is supported by the UV absorption spectra of **41–43**. Under the irradiation conditions using high-pressure mercury lamp and Pyrex filter (>280 nm), **41** and **42** competitively absorb UV light, but **43** does not absorb incident light. Similar photoreaction of the related compounds **47a–b** afforded pentacyclic compounds **48a–b** stereoselectively in 74% and 85% yields, respectively.

Photoreaction of compounds **49a–c**, which are connected two chromophores by an ether linkage, proceeded in a similar manner (Scheme 20.12). Namely, at the initial stage of the photoreaction, **50a–c** was predominantly produced, but prolonged irradiation led to an accumulation of **51a–c**. In such a reaction system in which both a fast reversible process and a slow irreversible process coexist, the microflow system is appropriate for the selective formation of the initial product.^{32,33} Under the batch conditions without stirring, the primary product is produced only near the surface of vessel at the initial stage of the photoreaction, then a secondary reaction proceeds faster than the diffusion of the primary product that has been already accumulated near the surface. On the other hand, in the flow system, selective

SCHEME 20.11

SCHEME 20.12

formation of primary product can be achieved by the quick outflow of the primary product from the reaction system.

Asymmetric induction in the intramolecular [2 + 2] photocycloaddition of **49b** by its incorporation in chirally modified zeolites has been observed (Scheme 20.13).³⁴ Photoirradiation of **49b**, included in NaY zeolites along with phenylalaninol **52**, gives **50b** with a maximum 15% ee. The degree of enantioselectivity was found to depend on the Si/Al ratio, the nature of cations in the zeolites, the structure of chiral inductors, and the molar ratio of substrate and chiral inductors.

A novel intramolecular [4 + 2] photocycloaddition between naphthalene and alkene was developed by Banerji et al. (Scheme 20.14).³⁵ When 2-methyl-2-ethenyl naphthalene-4-chromanone **53** in methanol or ethanol in the presence of H_2O was irradiated, alcohol-incorporated [4 + 2] photocycloadducts **55a–b** were produced in both 20% yields.

Intermolecular photocycloaddition of uracil derivatives to naphthalene and its derivatives was developed by Seki et al. UV irradiation of 6-chloro-1,3-dimethyluracil **57** with naphthalene **56** in nonpolar

SCHEME 20.13

SCHEME 20.14

SCHEME 20.15

solvents such as cyclohexane and benzene gave substitution product **58**, while photoreaction in acetonitrile or cyclohexane in the presence of trifluoroacetic acid gave 1,2-cycloadducts including cyclobutene ring **59** and **60** (Scheme 20.15).³⁶ In contrast, 5-fluoro derivative **61** reacts with naphthalene to give [4 + 2] cycloadduct **62**, whereas substitution product **63** was obtained in the presence of acid.^{37,38} In the photoreaction of 5-methyl derivative **64**, [4 + 2] photocycloadduct **65** was produced, but in the presence of 1,3-pentadiene as a triplet quencher, [2 + 2] photocycloadduct **66** was obtained.^{39,40} Photoreactions of 6-chloro derivative **57** with phenanthrene and pyrene were also investigated by them, which afforded [2 + 2] photocycloadducts at 9,10-position of phenanthrene and 4,5-position of pyrene.⁴¹

Novel photocycloaddition of *N*-methyl-2,3-naphthalenedicarboximide **67** was observed by Qing-Jian in 2007 (Scheme 20.16).⁴² When **67** was irradiated with excess amount of phenylacetylene **68**, hexacyclic adduct **69** was obtained in 68% yield. Structure of **69** was confirmed by x-ray crystallographic analysis, which contains three molecules of **68**.

Fujita et al. reported that confined cavities consisted from tri(4-pyridyl)triazine and Pd-TMEDA complex **70** is suitable media for [4 + 2] thermal (Diels–Alder) and [2 + 2] photocycloaddition reactions (Scheme 20.17).^{43,44} Suspending pyrene and *N*-cyclohexylmaleimide into **70** in aqueous solution forms ternary complex **71** in 81% yield. The aqueous solution was irradiated to give a complex **72** including cross-photocycloadduct indicating *syn* stereochemistry quantitatively. Efficient *syn*-selective and regioselective [2 + 2] photocycloaddition is also observed in fluoranthene-included complex **73**.

Helix structure of cholesteric phase influences stereochemistry of [2 + 2] photocycloaddition. Maeda and Mizuno et al. reported that photocycloaddition of cholesteryl cinnamate **76** with methyl 9-phenanthrenecarboxylate **75** under neat conditions at 150°C–170°C produced a 14% diastereomeric excess of **77** (Scheme 20.18).⁴⁵

SCHEME 20.16

SCHEME 20.17

SCHEME 20.18

20.4 Photodimerization of Anthracene Derivatives and Related Compounds

Anthracene and its derivatives are susceptible for photodimerization at their 9,10-position. For 9-substituted anthracene **78**, there are both possibilities upon photoirradiation to produce head-to-tail dimer **79** and head-to-head dimer **80** (Scheme 20.19). Intramolecular photodimerization of tethered two anthracenes **81** and photochemical and thermal cleavage of **82** are often utilized for photoswitching devices. There are excellent reviews treating this photoreaction,^{11,46–51} so only recent development is introduced.

Molecules tethering two naphthyl rings are less susceptible for photodimerization than anthracene analogues. Tung et al. reported photoreaction of **83** is very inert in homogeneous solutions, but photoreaction of **83** within supercages of NaY zeolite proceeds smoothly (Scheme 20.20).⁵² Tung also reported cucurbit[8]uril **86** can encapsulate **83** to make a stable 1:1 inclusion complex **84** in aqueous solution. Intramolecular photocycloaddition of **84** in aqueous solution proceeds with remarkable selectivity and efficiency.⁵³ Tung et al. also clarified that nanosized particles of modified silica with 3-ammoniumpropyl

SCHEME 20.19

SCHEME 20.20

SCHEME 20.21

residue **87**⁵⁴ and microemulsions of *N*-alkylimidazolium ionic liquid **88**⁵⁵ are effective for the regioselective photodimerization of 9-substituted anthracenes.

Intramolecular [4 + 4] photocycloaddition of **89** gave **90** and then **91** (Scheme 20.21).⁵⁶ This is called “molecular folding screen,” which can be unfolded by thermal cycloreversion.

Since [4 + 4] photodimerization of anthracene is an efficient and fast process, intramolecular photocycloaddition of anthracene and another chromophore competes with intermolecular photodimerization. However, Meier et al. recently investigated substituent effects of a benzene ring of **92** on selectivity between intra- and intermolecular photocycloaddition in detail (Scheme 20.22).⁵⁷ They concluded that methoxy groups on benzene ring of **92** made the photoreaction to unimolecular process to give **93** selectively, since high electron density of the benzene ring causes electron transfer from benzene ring to *S*₁ of anthracene moiety.

SCHEME 20.22

SCHEME 20.23

Studies of the photodimerization in crystalline state have also progressed. Trzop and Turowska-Tryk monitored structural change of the photoreaction of anthracenophane **96** in crystal in detail using x-ray diffraction in 2008 (Scheme 20.23).⁵⁸ The cell volume increased by 0.8% until the reaction was 40% complete, and afterward decreased by 1.6% during the remainder of the photoreaction. The distance between reacting carbon atoms was constant until 20% photoreaction progress, then decreased, and stabilized from 40% photoreaction progress. This phenomenon was explained by interplay between stress resulting from the presence of product molecules and the rigidity of reactant molecules.

Since pentacene is a powerful candidate for p-type organic semiconductor, its synthesis and crystal structure has attracted much attention. However, pentacene and its derivatives easily suffer oxygenation and photodimerization. Fallis et al. investigated regiochemistry of photodimerization of 2,9-diethynylpentacene **98** and its crystal packing in detail (Scheme 20.24).⁵⁹

2-Alkoxy-1-naphthamide **100** is potentially chiral because bond rotation between the naphthalene ring and the C=O(NR¹R²) group corresponds to enantiomerization of **100** (Scheme 20.25).⁶⁰ However, in solution, it racemizes easily. Sakamoto et al. found that recrystallization of **100** in hexane/chloroform mixed solvent gave crystals in a chiral space group, $P2_12_12_1$, it reveals that each single crystal was chiral and composed of one enantiomer. The half-life of the enantiomerization was 11.8 min when the crystals were dissolved in THF at 15°C, and the lifetime was lengthened with lowered temperature and

SCHEME 20.24

SCHEME 20.25

SCHEME 20.26

addition of MeOH. Asymmetric photocycloaddition of **100** with 9-cyanoanthracene **101** was achieved when some chiral crystals of (+)-**100** were allowed to react with **101** under photoirradiation to give **102** in 95% ee. Naphthamide derived from L-proline **103** exists as a mixture of diastereomers in (*S, aR*)-form and (*S, aS*)-form.⁶¹ Compound **103** also crystallized in a chiral space group $P2_1$ and formed the (*S, aR*)-conformation in the crystals. Photoreaction of the crystal with **101** diastereoselectively gave **104**.

Nakamura and Inoue reported that 2-anthracenecarboxylic acid **105** makes a stable 1:2 inclusion complex with γ -cyclodextrin (Scheme 20.26). Photodimerization of **105** included in γ -cyclodextrin gave photodimers **106**–**109**. The ee of chiral *syn*-head-to-tail dimer **106** was 41% at 0°C irradiation.⁶² Yields and ee of chiral *anti*-head-to-head dimer **107** increased by using 2-(dimethylamino)ethylamino-substituted γ -cyclodextrin.⁶³ γ -Cyclodextrins capped by arenesulfonyl groups could control orientation and ee of dimer **106**.⁶⁴ 2-Anthracenecarbonyl-substituted α -cyclodextrin⁶⁵ and human serum albumin⁶⁶ made the ee of **106** and **107** more than 90%. A chiral template **110** provides a novel hydrogen-bonding and shielding motif for enantioselectivity.^{67,68}

20.5 Photocycloaddition of Heteroaromatic Compounds with Unsaturated Compounds

In this section, recent advances in photocycloaddition of heteroaromatic compounds with unsaturated bonds will be introduced.

West et al. reported that photoreaction of **111** having substituted pyran-2-one and furan gave **113** via thermal decarboxylation of intramolecular photocycloadduct **112** (Scheme 20.27).^{69,70} Compound

SCHEME 20.27

SCHEME 20.28

113 reacted with MeLi to furnish triquinane compound **114** via β -elimination, 1,5-hydrogen shift, and transannular aldolization. Diastereoselectivity of the initial [4 + 4] photodimerization was investigated in the photoreaction of **115**.⁷¹ *Endo*-selectivity of the **116** was obtained via *endo*-TS, and the diastereoselectivity depends on the solvent used.

Mizuno et al. reported that photocycloaddition of furan **118** to naphthalene derivatives **117a-e** afforded caged products **119a-e** in high yields when the naphthalene derivatives have electron-withdrawing groups at 2- or 2,3-position (Scheme 20.28).⁷² For the formation of caged products **119**, dipole moments of each substrate were important.

Garcia-Garibay reported photoreaction of ketone **120** having thiophene and *S,S*-dioxothiophene (Scheme 20.29).⁷³ Rather than the expected photodecarbonylation to give **121**, UV-vis irradiation of **120** led to the intramolecular [2 + 2] photocycloadduct **122** in quantitative yield both in solution and crystalline solid state.

SCHEME 20.29

SCHEME 20.30

Photochemical [2 + 2] cycloaddition of alkynes and butadiynes to benzo[1,2-*b*:4,5-*b'*]dithiophene **123** was investigated by Neckers et al. (Scheme 20.30).⁷⁴ Irradiation of **123** and **124** for 16 h gave a rearranged product **126** in 16% yield. Photoreaction of **123** with diarylbutadiyne **128** gave cyclobutene compounds **129** and **130**.

As for pyridine derivatives, Sakamoto et al. has already reported photocycloaddition of 2-cyano-3-alkoxypyridine derivatives **131** with methacrylonitrile **132** as an electron-poor alkene, in 1996, to give bicyclic azetine **133**, 3-acetyl-4-amino-1,5-dicyano-2,5-dimethylcyclohexa-1,3-diene **134**, and rearranged pyridine derivative **135** (Scheme 20.31).⁷⁵ They confirmed that **134** is produced by hydrolysis of **133**. The compound **133** might be formed via [2 + 2] photocycloadduct **136** at 2,3-position of **131**

SCHEME 20.31

SCHEME 20.32

and azacyclooctatriene derivative **137**. They reported that photoreaction of **138** with vinyl ethers **139**, which are electron-rich alkenes, gave azacyclooctatriene derivative **140** (when $R^4 = \text{H}$) and 2-azabicyclo[4.2.0]octa-2,7-diene **141** (When $R^4 = \text{Me}$).⁷⁶ These products are produced from [2 + 2] photocycloadducts **143** and **144**, respectively. PM3 calculation showed that $\Delta\Delta E$ value between lower SOMO of the excited state of **138** and HOMO of **139** is smaller than the value between higher SOMO of the excited state of **138** and LUMO of **139**. Coefficient at the C-3 position of **138** is bigger than those at other positions in lower SOMO of the excited state of **138**. So they proposed a mechanism that both **143** and **144** may be produced from biradical **142**, which will be formed by C-3 attack of **139** to the excited state of **138**.

Booker-Milburn reported that photoirradiation of benzotriazole **146** with a variety of maleimide derivatives leads to regio- and stereoselective formation of [2 + 2] photocycloadduct **150** (Scheme 20.32). They explained this high selectivity by tautomerization from 1*H*-benzotriazole **146** to 2*H*-benzotriazole **147** and high double bond character of the reactive position of **147**.⁷⁷ Novak and Kovac demonstrated the correlation of the double bond character of **147** with complete regioselectivity in this photoreaction by UV photoelectron spectroscopy and *ab initio* calculation in 2009.⁷⁸

Acridizinium ion **151** has an isoelectronic structure with anthracene (Scheme 20.33). Since **151** undergoes [4 + 4] photodimerization to give **152** and its regioisomers, and thermal cycloreversion of **152** recovers **151**, the reactions can be used for photochromic systems.⁷⁹ Tbt-substituted 9-silaanthracene **153** is a stable crystalline compound synthesized by Tokitoh et al.⁸⁰ When degassed benzene-*d*₆ solution of **153** in a sealed Pyrex tube was irradiated with light of $\lambda = 300\text{--}500\text{ nm}$ at room temperature, the orange color of **153** disappeared and a new species, 9,10-dewar-9-silaanthracene **154** was formed exclusively. The compound **154** can be detected by ¹H, ¹³C, ²⁹Si NMR, and UV-vis spectroscopy, but could not be isolated as a stable compound and undergo gradual thermal tautomerization into **153** even at -80°C in hexane. Conversion of **153** to its dimer **155** can be achieved by 110°C for 15 days in benzene-*d*₆ solution (42% yield) or 180°C for 1 h in the solid state (58% yield). Dimer **155** is a stable compound and no cycloreversion to **153** was observed in 1,2-dichlorobenzene-*d*₄ solution even at 200°C .

SCHEME 20.33

20.6 Photocycloaddition and Photoalkylation of Aromatic Rings with Cyclopropanes

Cyclopropanes, whose bonding and antibonding σ -orbitals are banana shaped, are expected to behave chemically like unsaturated compounds. However, only a few reports have appeared describing photoreactions between aromatic compounds and cyclopropanes. In 1986, Mizuno et al. reported (4 + 3) photocycloaddition of 9,10-dicyanoanthracene **156** with 1,2-diphenylcyclopropane **157** in degassed acetonitrile (Scheme 20.34).^{81,82} 1-Amino-2-phenylcyclopropanes⁸³ and methylenecyclopropanes⁸⁴ also react with **156** in a similar manner to give [4 + 3] photocycloadducts.

A novel [3 + 2] photocycloaddition between cyclopropane derivatives with aromatic rings was developed by Mizuno.⁸⁵ 9-Cyanophenanthrene **160** reacts with 1,2-dianisylcyclopropane **161** to give [3 + 2] photocycloadduct **162** in a stereoselective manner (Scheme 20.35). From the *cis*-stereochemistry of **162**, structures of by-products **163–165**, substituent effect of 1,2-diarylcyclopropane, and control experiments, they proposed a reaction mechanism involving stepwise C–C bond coupling via singlet exciplexes **166**, **167** and biradicals **168**, **169**.

Photoreaction of a naphthalene derivative **117e** with methoxy-substituted 1,2-diarylcyclopropanes led to the formation of photoalkylated product **171** with excellent regioselectivity (Scheme 20.36).^{86,87}

SCHEME 20.34

SCHEME 20.35

SCHEME 20.36

As also seen in the photoreaction of **160**, singlet exciplex **172** and biradical **173** are postulated as intermediates of the photoreaction. The secondary C–C bond formation, which can be seen in the reaction of **160**, did not occur but intramolecular hydrogen transfer took place to give **171**.

21.1 Introduction

The di- π -methane rearrangement consists, as its name implies, of a photochemical reaction of a reactant with two π moieties bonded to a single carbon, this is generally sp^3 -hybridized and hence a “methane” atom. The reaction is one of the most common, most versatile, and best understood of photochemical transformations.

21.2 Discovery and Mechanism

The beginnings go back to the photolysis of barrelene, which leads to semibullvalene in an intriguing process [1]. This is shown mechanistically in [Equation 21.1](#). Barrelene, of course, has more than two π groups bonded to each bridgehead carbon and thus uses only pair set of these. This reaction proceeds via the triplet with an acetone sensitizer.

Probably the first di- π -methane examples [2,3] are depicted in Equations 21.2 and 21.3. But these “Type-A” and “Type-B” rearrangements involve excitation of the enone moiety to an $n\text{-}\pi^*$ triplet state rather than the more common $\pi\text{-}\pi^*$ excitation; and we will arbitrarily not include these in our present discussion. Nevertheless, these rearrangements, involving a pair of π groups bonding to an sp^3 -hybridized carbon led us to look for generality of the reaction. Another early example of the di- π -methane rearrangement is illustrated in Equation 21.4 [4]. In contrast to the Barrelene example, this acyclic di- π -methane reactant, the Mariano diene, utilizes the singlet excited state (i.e., S_1). Again due to symmetry there is only one available mode of ring opening of the cyclopropyldicarbonyl diradical species. However, in the case of the unsymmetrical diene in Equation 21.5 there are two a priori ways, a and b, for cyclopropyldicarbonyl ring opening [5]. The cyclopropyldicarbonyl diradical species selects only one of these (i.e., b). The reaction regioselectivity results from the demand for maintenance of benzhydryl odd-electron delocalization; thus the benzhydryl odd-electron is not used by the cyclopropyldicarbonyl diradical. This was an early example of regioselectivity. One of two examples by Griffin and coworkers [6] is shown in Equation 21.6. Although no mechanisms were advanced at the time, we can see that the usual di- π -methane mechanism suffices to lead to the observed photoproducts using the mechanism we write in Equation 21.6.

However, we cannot assume that all 1,4-di- π -methane systems proceed via the general mechanism we have suggested. One example [7] is seen in Equation 21.7 where a central hydrogen migrates to the terminus of a diphenylvinyl group in a sigma plus pi rearrangement. Lacking central alkyl substitution, the molecule does not undergo a di- π -methane rearrangement. Of course we cannot extrapolate this result to all 1,4-di- π systems. For example, one reaction (see Equation 21.8) studied by Griffin [6b] may follow the 1,4-di- π -methane mechanism or, instead, as in Equation 21.7, may proceed via the $\sigma\text{H} + \pi$ route. Deuterium labeling is needed to determine which mechanism is followed.

21.3 Regioselectivity in the Di- π -Methane Rearrangement

In pursuing the regiochemistry of the di- π -methane rearrangement further, we looked at the case of a Mariano-type reactant, however, with *p*-cyano substitution on one-half of the molecule [8]. Scheme 21.1 shows the two alternative pathways, **a** and **b**, leading to two possible vinylcyclopropanes. The experimentally observed product arises from pathway **a** when the aryl group is *p*-cyanophenyl and from pathway **b** when the aryl group is anisyl. In the former the odd-electron density delocalized into the cyano group is preserved. It is seen that this route avoids a 1,3-diradical species in which the cyano group no longer interacts with the odd-electron density.

Scheme 21.2 presents some further examples [9] of regioselectivity. In the case where there is a terminal methylene (i.e., X = H), path **a** uses electron density that is originally heavily diffused throughout the benzhydryl moiety, while path **b** utilizes density that is largely concentrated at the methylene group.

SCHEME 21.1 Regioselectivity with *p*-cyano substitution.

SCHEME 21.2 Further examples of regioselectivity.

In path **a** the electron density in the benzhydryl group thus is largely lost as is the energy of benzhydryl delocalization. Hence path **b** is preferred. Where X is cyano or methoxy prediction is more difficult. However, cyano groups are particularly efficient in delocalizing electron density and thus it is not surprising that path **a** is now preferred. In the methoxy case the same factors as for X = H dominate resulting in preference for path **b**.

21.4 Reality of Diradical Intermediates in the Di- π -Methane Rearrangements

One may consider whether the diradical species written in the aforementioned mechanisms are actual intermediates, are merely points on the reaction hypersurface, or if the mechanisms involve instead a sigma plus pi process as suggested by Woodward and Hoffmann [10] as an alternative. In the case of barrelenes, there is evidence on this point, demonstrating that the triplet diradicals proposed earlier are indeed involved. Thus the azo-bridged precursor, on triplet sensitization, affords the same ratio of two dimethyl naphthosemibullvalenes as obtained from the dimethyl naphthobarrelene itself (Scheme 21.3) [11]. Two independent approaches to the same species will give the same partition of products only if that species is of appreciable lifetime and thermally equilibrated as observed here. Hence, it is clear that the photochemistry of the naphthobarrelene itself proceeds via the same triplet (i.e., T_1) 1,3-diradical **3**. This species must then be an energy minimum. With xanthone T_2 becomes involved.

SCHEME 21.3 Evidence for a common triplet 1,3-diradical (4 or 5).

21.5 Reaction Stereochemistry

In the di- π -methane rearrangement, there are several sites where stereochemistry is involved. One is at carbon-5 (the carbon ending as part of the product cyclopropyl ring; Scheme 21.4). In Equations 21.9 and 21.10, it is seen that with *cis*-styryl the phenyl becomes *cis* on the three-ring, while a *trans* phenyl becomes *trans*. In Equations 21.11 and 21.12 we note the experimental observation of inversion of configuration at C-5, the methane carbon. In inspecting the basis set of p and hybrid orbitals involved in the rearrangement, as drawn in Scheme 21.5, we see an overlapping sequence of localized orbitals 1-2-3-4-5 in the reactant with orbital 3 being at the “methane” carbon. As the reaction begins, orbitals 2 and 4 begin to overlap and also 5 and 6 and 1 and 3 to give a cyclic array of 1-2-4-5-6-3-1. Inspection of this cycle shows a single plus-minus overlap (i.e., between 5 and 6) and thus a Möbius array [12]. The bonding between orbitals 1 and 3 is disrotatory in closing a three-ring and involves inversion of configuration at the methane carbon (here 3). Also, the substituent R_2 , which is *trans* to the vinyl group at 4-5 in the reactant, becomes *trans* to vinyl in the photoproduct.

We count 6 electrons in the cyclic array (i.e., 4 electrons in the two reactant π bonds and 2 in the 3-6 σ bond). With 6 electrons in the Möbius cycle, the reaction is excited state “allowed.” Finally, the original stereochemistry of the vinyl group is maintained despite the original p bond between orbitals 4 and 5 being replaced by one resulting from orbitals 5 and 6. If a conrotatory stereochemistry were to be followed the reaction would be forbidden and a reaction course in any case not experimentally observed.

SCHEME 21.4 Stereochemistry.

SCHEME 21.5 Basis orbital view giving rise to inversion at C-3.

21.6 Multiplicity Dependence of Regioselectivity

One interesting case is the reaction of 1,1,3,3-tetraphenyl-5,5-dicarbomethoxy-1,4-pentadiene in Scheme 21.6. A direct irradiation proceeding via S_1 results in scission of bond **a** while a sensitized irradiation involving T_1 leads to fission of bond **b** [13].

Another example of multiplicity dependence [16] is outlined in Scheme 21.7. Here direct irradiation affords three products, including one arising from phenyl–vinyl bridging and two from vinyl–vinyl bonding. Unzipping of the cyclopropyldicarbonyl diradical after vinyl–vinyl bonding leads 3:1 to the isomer with cyano on the three-membered ring. This is reversed in the triplet.

SCHEME 21.6 Multiplicity dependence of a di- π -methane rearrangement.

SCHEME 21.7 A further example: regiochemistry versus multiplicity.

21.7 Detailed Reactivity of Intermediate Diradicals in the Barrelene to Semibullvalene Rearrangement

We need to begin by recognizing that the behavior of electronically excited states, and thus photochemistry, is subject to two forms of control. As noted throughout our early reports, excited states follow low-energy pathways and avoid energy barriers. Additionally for singlets, where nearby conical intersections or avoided crossings present themselves, a pathway to the ground state surface results. Similarly for triplets, intersystem crossing (ISC) may lead to the ground state surface. In both singlet and triplet cases conversion to S_0 may lead back to ground state reactant or to ground state product depending on the location of the S_0 species when formed. The former is most likely when conversion to S_0 occurs prior to encountering a ground state barrier and the latter is most likely when conversion to S_0 occurs after encountering a ground state barrier and when the geometry is close to that of the product.

In the di- π -methane rearrangement the two intermediate species—diradical 1 and diradical 2—are particularly subject to consideration. Scheme 21.3 has noted evidence for intervention of diradical 1 in the reaction of benzobarrelenes. We now turn to Scheme 21.8 where the diradicals arising from barrelene, benzobarrelene, and 2,3-naphthobarrelene are generated from azo precursors [14]. We note that loss of nitrogen in the ground state by warming leads to reversion to the corresponding barrelene. While this may be envisioned, at one extreme, as a concerted reverse electrocyclic [3σ 6 electron] Hückel process, it may similarly be pictured at the other extreme as proceeding by loss of nitrogen to afford the diradical 1. It has been noted in our earlier work that there are possible all gradations between these alternatives. This process affords ground state (S_0) barrelene. If the S_0 diradical is truly involved, we would still anticipate formation of the barrelenes. This reversion of the 1,4-diradical on the S_0 surface indicates a ground state barrier between this diradical and photoproduct. The corresponding triplets, obtained by sensitization, lead nicely to the corresponding semibullvalenes rather than the Grob 1,4(2,3) fragmentation (Scheme 21.9).

Further, the triplet diradicals 1 and 2 were determined computationally to be energy minima [11,16,17] and close to degenerate with the S_0 ground state surface. With the knowledge (*vide supra*) that the S_0 species with the geometry of diradical 1 undergoes reversion to the reactant barrelene, it is clear by default that intersystem crossing to ground state must occur later once diradical 2 is formed [11]. Computation of the spin-orbit coupling at these the two stages of reaction, affording diradical 1 and diradical 2, reveals that the SOC for diradical 2 is much larger.

SCHEME 21.8 Generation and behavior of diradical 1.

SCHEME 21.9 Triplet Diradical 1 giving di- π -methane behavior and not Grob 1,4(2,3) fragmentation.

SCHEME 21.10 The unusual pathway for the photolysis of tripterycene.

A further finding with regard to the three systems in Scheme 21.8 was that all the T_1 diradicals 1 are subject to a Jahn–Teller distortion in which one of the π bonds is stretched. The triplet computations on diradicals 1 and 2 were done at the CASSCF(6,6)/6-31G* level.

A particularly interesting reaction (Scheme 21.10) involves the photolysis of tripterycene **1**. This had been reported by Turro and Friedman [18] as giving photoproduct **4** and not the anticipated di- π -methane product **3**. It was suggested that, once formed, **3** undergoes a sigmatropic rearrangement to **4**. Note Mechanism A in Scheme 21.10. However, in a series of thorough studies, Iwamura [19] has shown that a different route is followed, namely Mechanism B in Scheme 21.10. This proceeds via the carbene **5**, which can be trapped by methanol to afford the benzylic methyl ether **6**. In a control experiment, Iwamura [19] showed that photolysis of **4** in methanol does not lead to trapping of the carbene. And thus the benzylic methyl ether is not formed from photoproduct **4**. In the absence of methanol, photoproduct **4** results. The reaction mechanism is seen to involve benzo–benzo bridging to afford diradical **2**, which can extrude the bridgehead carbon leading to carbene **5**. The divalent carbene carbon then attacks one benzo ring to form photoproduct **4**.

21.8 Aryl-Vinyl Di- π -Methane Rearrangements

One simple typical example involves phenyl–vinyl bridging [14–20] and is illustrated in Scheme 21.11 along with the reaction mechanism; this is the same mechanism we have postulated for the reaction of Griffin and shown in Equation 21.6. Thus in Scheme 21.11 the lower energy chromophore

SCHEME 21.11 The phenyl-vinyl di- π -methane rearrangement.

SCHEME 21.12 Further examples.

is the diphenylvinyl group that is excited with formation of species 2. Phenyl–vinyl bridging leads to singlet diradical 3 with loss of benzenoid aromaticity. In comparing electron redistributions a and b in this diradical, process a is seen to restore benzenoid aromaticity and retains benzhydryl delocalization while process b does not restore benzenoid aromaticity and loses the delocalization of the benzyhydril moiety. Scheme 21.12 provides further examples.

21.9 Triplet Reactivity

Although the generalization has been drawn that cyclic di- π -methane reactants such as barrelene react via triplets while acyclics react via singlets, the source of this reasoning needs to be recognized. Thus the competing process for triplets of free-rotor energy dissipation is inhibited for the cyclic π systems and for severely hindered acyclic systems where double bond rotation is impossible or difficult. Additionally, it needs to be recognized that where the quantum yield for the triplet process is finite, extended irradiation can be synthetically successful as long as competing processes do not do more than effect *cis-trans* interconversion. Note also the examples in Scheme 21.12.

Indeed, there are examples of acyclic di- π -methane rearrangements proceeding via the triplet with appreciable efficiency. Thus, although the reactant in Equation 21.18 is acyclic, we note that excitation will primarily affect the diphenylethylene moiety and not the less conjugated vinyl. Thus free rotation will be slower. Most interestingly, there is a temperature effect in which the quantum yield is increased fivefold (27°C–73°C) [9].

Another example [21] is that of *p*-cyanophenylbutene (Equation 21.19), which, on acetone sensitization, rearranges with a quantum yield of 0.71. The *meta*-isomer has a quantum yield of 0.25.

It seems that the potential free-rotor C=CH₂ is a high-energy portion of the molecule and with its excitation being inaccessible, energy dissipation by the free-rotor effect is lost. A further example is seen in the tetraphenyl example [21] in Equation 21.20. The triplet quantum yield is 0.42, which is remarkably high. Electronic factors have been considered. However in this case steric factors are involved. A potential free-rotor, namely the Me₂C=C group is substituted on the methane carbon, and that carbon bears three large substituents—phenyl, phenyl, and diphenylvinyl. Thus the free-rotor is *gauche* to two of these and is sterically hindered. Additionally, the dimethyl vinyl is a high-energy chromophore. The reaction in Equation 21.21 [16] has a quantum yield of 0.79, which is even more remarkable and there seems to be incursion of an electronic factor as well as the steric factor just mentioned.

SCHEME 21.13 Phenyl migration from the singlet and also diene rearrangement from the triplet.

An additional point of interest is that the direct irradiation of the reactant in Equation 21.20 differs in additionally having product deriving from phenyl migration (Scheme 21.13). Further, the triplet leads additionally to the rearranged di- π -methane diene as depicted in Scheme 21.13.

21.10 Reaction Rates

Considerable information can be obtained from reaction rates in the di- π -methane rearrangements. In principle, one should correlate mechanistic reactivity with reaction rates rather than quantum yields. We now consider the three examples in Equation 21.22.

For these three reactions the regiochemistry, the quantum efficiency, the multiplicity, and the excited state reaction rates were studied. We discuss the direct, singlet processes first. The room temperature quantum yields were ϕ (1, parent) = 0.011, ϕ (2t, *trans* CN Diene) = 0.36 and ϕ (2c, *cis* CN Diene) = 0.20,

ϕ (**3t**, *trans* MeO Diene) = 0.51, ϕ (**3c**, *cis* MeO Diene) = 0.050. However, it has long been recognized that inherent reactivity is signified by reaction rates and not quantum yields. The latter give only the reaction rates relative to all rates including decay.

Single-photon counting reaction rates for the singlets were k_r (**1**, parent) = $4.7 \times 10^8 \text{ s}^{-1}$, k_r (**2t**, *trans*) = $1.5 \times 10^{10} \text{ s}^{-1}$, k_r (**2c**, *cis*) = $8.0 \times 10^9 \text{ s}^{-1}$, and k_r (**3t**, *trans*) = $1.8 \times 10^9 \text{ s}^{-1}$ [9]. It is seen that the cyano di- π -methane dienes are the most reactive, the methoxy dienes next, and the parent hydrocarbon the least.

On sensitization, the cyano and methoxy dienes gave only *cis-trans* isomerization. However, in the case of the parent diene **1** an exciting result was encountered. The parent diene did give the same photoproduct as obtained on direct irradiation (note Equation 21.22) and with the same quantum efficiency, $\phi = 0.011$, as in the direct irradiation. While one might be tempted to conclude from this that both direct and sensitized reactions proceed via the same, triplet excited state, this is not the case as seen in the differences in temperature dependence. In an increase in temperature from 27°C to 73°C, the quantum efficiency in the direct irradiation was unchanged while in the sensitized reaction the efficiency increased from $\phi = 0.011$ to $\phi = 0.058$, a fivefold increase. One might attribute this to a temperature dependence of sensitization efficiency except that it has been demonstrated that energy transfer has unit efficiency.

Thus with direct irradiation showing no temperature dependence and the sensitized, T1, reaction exhibiting the fivefold effect, it is clear that the direct irradiation is a singlet process, that is, S₁.

Of course, the temperature dependence of the T1 reaction signifies that there is an energy barrier for reaction while the lack of one for S1 shows that this process has none. But proceeding further, we note that the temperature dependence of the triplet di- π -methane rearrangement leads to a 7.5 kcal/mole Arrhenius activation energy. This requires the assumption that the rate of radiationless decay of the triplet is temperature independent; otherwise a still higher activation energy results.

Most interesting are the results of Lewis [22] who found the singlet reaction of 1,3-diphenyl-3,3-dimethylpropene **1** (note Equation 21.23) to be temperature dependent with an activation energy of 1.9 kcal/mole; and with varying substitution at the methane carbon similar values were obtained. In these cases the triplet did not exhibit temperature dependence.

FIGURE 21.1 Excitation of the cyclopropylidene diradical moiety.

Some items are particularly relevant [9]. One item is computational. Initially the π bonds are at carbons 1–2 and 4–5 and excitation is largely there. Thus for the diphenylvinyl type di- π -methane rearrangements, it is not surprising that computations reveal the vertical (i.e., initial) excitation is largely located in the diphenylvinyl moiety. What is especially interesting is that after π - π bridging excitation is found to reside in the cyclopropyldicarbinyl group. This, perhaps, is not that surprising since the cyclopropyldicarbinyl diradical moiety (note Figure 21.1), in the limit without delocalization with the orbitals in the cyclopropyl group, would have a pair unconjugated p-orbitals and complete degeneracy of HOMO–LUMO. Additionally, it is seen that the ground state S_0 is antibonding between atoms 2 and 4; but S_1 is bonding between these centers. Herein lies the basis for vinyl–vinyl or phenyl–vinyl π - π bonding in the di- π -methane rearrangement.

21.11 Conclusion

The di- π -methane rearrangement can be seen to be particularly general and subject to mechanistic understanding. The reaction is successful with a broad variation structurally and with singlet and triplet multiplicity. Patterns of behavior are seen experimentally and follow computational exploration.

22.1 Introduction to ODPM Rearrangement

Carbonyl compounds played an important role and became part of the leading research domain of organic photochemistry. Particularly, β,γ -unsaturated carbonyl compounds have attracted more attention. These β,γ -unsaturated carbonyls exhibit a variety of photochemical processes like (a) acyl migration, (b) oxa-di- π -methane (ODPM) rearrangement, (c) decarbonylation, (d) epimerization, (e) cycloaddition, (f) Norrish type I and type II processes, (g) *cis-trans* (*E-Z*) isomerization, and (h) reduction. Among the various photochemical processes of β,γ -unsaturated carbonyls, the ODPM rearrangement has attracted the attention of various researchers. This is because photochemical ODPM rearrangement provides high yields of products having synthetic exploitation, good photochemical quantum yields, making complex molecules in a very simple way, maintaining excellent selectivity, understanding the role of various excited states (involving multiplicity), and also understanding the role and link between carbonyl and olefin chromophores within the molecule to predict the reactivity.

22.2 Historical Perspective

The photochemical rearrangement of β,γ -unsaturated carbonyl compounds involving 1,2-acylmigration coupled with cyclization leading to the formation of three-membered ring is termed as “oxa-di- π -methane (ODPM)” rearrangement. The photochemical ODPM rearrangement is analogous to the “di- π -methane”

SCHEME 22.1 First example of ODPM rearrangement.

rearrangement (see the other chapter) reported earlier. The first example of an ODPM rearrangement was reported in 1966 for β,γ -unsaturated ketone (Scheme 22.1) and it went largely unnoticed.

The first mechanistic pathway was suggested by Swenton² and later Givens³ explained the mechanism for the photochemistry of butyrolactone (Scheme 22.1) derivative as analogous to di- π -methane (DPM) rearrangement. Immediately Dauben⁴ came up with a description for the photoreaction as “oxa-di- π -methane (ODPM)” rearrangement. Since then several researchers got involved in this ODPM rearrangement research domain and this resulted in a large number of publications in this area. The preference to conduct ODPM rearrangement with β,γ -unsaturated carbonyls is increasing, because of its very good chemical yields, photochemical quantum yields, and observed selectivity, which encouraged many researchers to work in this area of research. The ODPM rearrangement reaction has been successfully applied for the synthesis of many complex natural products and other intermediates, which are otherwise difficult to obtain by other means. Interestingly, the ODPM rearrangement originates from triplet excited manifold and this became an advantage to conduct photoreaction under triplet-sensitized conditions with higher yields. Several reviews^{5–23} have appeared on this subject of ODPM and DPM rearrangement during the last three to four decades. In this chapter, we discuss a brief introduction, mechanistic aspects, various examples, scope and limitations, representative experimental procedures, and targeted structures. Selectivity and stereochemical aspects are highlighted wherever appropriate and necessary. This is a short review highlighting the basic fundamental aspects of ODPM rearrangement to enthuse new researchers into this research domain. For more details, the reader may consult various review articles and book chapters available in the literature.^{5–23}

22.3 Reactive Excited State

ODPM rearrangement reaction is found to be originating from triplet excited state in almost all the compounds studied. Several model compounds^{24–26} (Scheme 22.2) displayed that ODPM rearrangement can be conducted by direct excitation or more conveniently by triplet-sensitized conditions. Under direct excitation conditions the substrate undergoes intersystem crossing in the singlet excited state, leading to formation of triplet excited state and then the ODPM rearrangement follows (Scheme 22.2). Under triplet sensitization conditions, the triplet excited state of sensitizer transfers energy to substrate molecule (triplet–triplet energy transfer) and then the ODPM rearrangement is observed (Scheme 22.2). The direct excitation experiments may be ambiguous with respect to involvement of excited singlet or triplet state responsible for the observed ODPM rearrangement. Detailed investigations on a set of model compounds^{25,27,28} (Scheme 22.3) informed that indeed the ODPM rearrangement originates from the triplet excited state. It is well documented that $\pi\pi^*$ triplet is responsible for ODPM rearrangement based on low-temperature phosphorescence measurements and theoretical and mechanistic studies.

A recent report by Diego Armesto²⁹ clearly pointed out the important role of “energy of triplet sensitizer” on the ODPM rearrangement reactivity of β,γ -unsaturated carbonyls (Scheme 22.4). Among the sensitizers employed, the thioxanthone ($E_T = 63$ kcal/mol) is found to be effective for the observed

SCHEME 22.2 Model compounds of ODPM rearrangement.

SCHEME 22.3 Model compounds defining "triplet" as reactive state.

SCHEME 22.4 Role of sensitizer in ODPM rearrangement.

ODPM rearrangement reactivity (Scheme 22.4). The authors²⁹ have used mainly free rotor effect (E/Z isomerism) and also 1,3-acyl migration as dominating photochemical pathways for the compounds shown in Scheme 22.4.

These observations definitely point out to verify the ODPM rearrangement activity for the β,γ -unsaturated carbonyls^{30–32} earlier reported to be not active compounds (Scheme 22.5). Triplet sensitizer energy-dependent ODPM rearrangement is reported for quinuclidinone (azabicyclo- β,γ -unsaturated ketone), where the authors³³ have successfully conducted ODPM rearrangement using triplet sensitizer acetophenone, but not with acetone as triplet sensitizer (Scheme 22.6). The efficiency of ODPM rearrangement is found to be increased (compared to solution-phase photolysis) upon confinement of

SCHEME 22.5 β,γ -Unsaturated ketones not active toward ODPM rearrangement.

SCHEME 22.6 Role of sensitizer in ODPM rearrangement.

SCHEME 22.7 Improvement in reactivity of ODPM rearrangement upon confinement.

substrate and triplet sensitizer (Scheme 22.7) in a zeolite.³⁴ Considering the data given earlier, the reactive excited state involved in these β,γ -unsaturated ketones leading to ODPM rearrangement is a triplet excited state of $\pi\pi^*$ origin. Further, it was observed that a sensitizer with suitable triplet energy is also another condition to conduct the ODPM rearrangement efficiently.

22.4 Theoretical Aspects

The majority of experimental results reveal that direct irradiation on β,γ -enones yields mainly the [1,3]-acyl shift product where as triplet sensitization yields the ODPM product.^{24,35} A possible explanation for the divergent behavior of β,γ -unsaturated ketone singlet and triplets has been proposed by various groups. Schuster et al.³⁶ suggested that different spin density distributions in the excited singlet and triplet states lead to differing initial bonding interactions and ultimately to different products and implicitly it is assumed that both excited singlet and triplets were $n\pi^*$ excited states. Later, Houk and coworkers³⁷ explained based on the differences in the electronic configurations of the excited states and by considering the concept of probable bonding charges in the excited state can be predicted based on the bond order differences between the ground state and the excited state. However, the selectivity of singlet and triplet states yielding [1,3]-acyl and ODPM products is not universal. In few instances, the ODPM rearrangement is formed on direct photolysis of certain β,γ -enones, while the [1,3]-acyl photo-product has been observed on triplet sensitization.^{25,26,38,39} Although the existence of intersystem crossing (ISC) is assumed to be an integral part of these mechanisms for the triplet-sensitized reactions, Schaffner and coworkers⁴⁰ admit that it is known neither by which mechanism the T_1 and T_2 species return to S_0 nor whether energy transfer or chemical scavenging (or both) are involved in the quenching of these excited states. Pertaining to mechanism based on theoretical calculations, the literature is very limited.⁴¹⁻⁴⁴ Robb and coworkers explored the excited state reaction pathways and decay mechanisms for the simplest model β,γ -enone, but-3-enal using quantum chemical computations at multiconfiguration self-consistent field (MC-SCF).⁴¹ The authors have proposed that the ODPM reaction path involves

FIGURE 22.1 Biradical and concerted mechanism proposed based on MCSCF computations.

two biradical intermediates **A** and **B**, with **A** being the primary photoproduct and **B** being a short-lived 1,3-biradical that rapidly produces the final three-membered ring product (Figure 22.1). This occurs as intermediates in a three-step process. The reaction profile shows that the accessibility of the decay region for the ODPM reaction is controlled by an excited state barrier. The $^3(\pi\pi^*)$ surface is the lowest energy excited state surface at all geometries before the conical intersection region, and it is usually assumed that the majority of ODPM product is formed from this surface on triplet sensitization. In the model system studied by authors, the barrier to $^1(n\pi^*)$ fragmentation is about 2 kcal/mol lower than the $^1(n\pi^*)$ ODPM reaction barrier, such that the dissociation–recombination reaction can compete effectively with the ODPM reaction. However, this competition will be sensitive to perturbations introduced by substituent effects.⁴¹

The authors have concluded that the $^3(\pi\pi^*)$ ODPM rearrangement and the $^3(\pi\pi^*)$ [1,3]-acyl shift reaction both correspond to mechanisms involving ISC at a crossing region (**A** and **C**, respectively), although the difference in barrier heights is only 2 kcal/mol in favor of the ODPM reaction (Figure 22.1). Further, the transition state leading to dissociation on the $^1(n\pi^*)$ surface lies 2 kcal/mol below the transition state for the ODPM path. This is consistent with the fact that on direct photolysis acyclic enones give exclusively the [1,3]-acyl shift product via dissociation and recombination. However, in other cases both steric and dynamic effects could change the order of these barriers such that both the ODPM reaction and the stereospecific [1,3]-acyl shift reaction could also occur on direct photolysis.⁴¹

Robb and coworkers have proposed that the mechanism of triplet reactions is a stepwise process with the formation of the biradicaloid intermediate **A** where the stereochemistry of the reactant can be lost, but this decay can be quite efficient.⁴¹ On the other hand, singlet ODPM reaction will be essentially concerted since decay via the S_1/S_0 conical intersection will occur within one vibrational period and leads to the S_0 intermediate, which will immediately rearrange. The lack of selectivity of direct versus sensitized irradiation, the sensitivity of the reaction outcome to substituents, and the degree of stereospecificity are therefore related to the character of these decay regions.⁴¹

22.5 Mechanistic Details

There are at least three types of mechanisms discussed in order to explain the ODPM rearrangement. The first mechanism (Scheme 22.8) is radicaloid in nature: involves a Norrish type I cleavage leading to the formation of acyl and allyl radical and recombination of these radicaloid species to the ODPM rearrangement product in two ways.

SCHEME 22.8 Radicaloid mechanism for ODPM rearrangement.

SCHEME 22.9 Concerted mechanism for ODPM rearrangement.

SCHEME 22.10 Radicaloid and concerted mixed mechanism for ODPM rearrangement.

The second mechanism is a concerted (Scheme 22.9) rearrangement involving symmetry-allowed processes. The third mechanism (Scheme 22.10) is a mixed mechanism involving one concerted process leading to radicals and followed by radical combination to give ODPM rearrangement products. These different mechanistic routes were applied in order to explain selectivity phenomena within the ODPM rearrangement. Interestingly, Armesto¹⁶ and his group introduced photochemical electron transfer type mechanism involving radical-ion intermediates in DPM and aza-di- π -methane (ADPM) rearrangement reactions. Many reports suggest that radicaloid intermediates are very much involved in these ODPM rearrangement reactions.⁴⁵⁻⁴⁷ A concerted mechanism is proposed to explain the results of high degree of specificity observed in a set of bicyclic substrate compounds shown in Scheme 22.11. Support for the mixed mechanism came from the example shown in Scheme 22.12. These mechanisms are still a matter of debate and create enough curiosity to continue creative and innovative research in order to understand the ODPM rearrangement. Interesting questions are, why β,γ -unsaturated ketone upon excitation largely prefers ODPM rearrangement pathway, even though several other pathways are available that in general dominate the photochemistry of ketones? Also how the excitation energy is localized within the molecule and utilized to cleave (mode selective) a particular chemical bond? One study⁴⁸ reported that ODPM rearrangement is also possible from the singlet excited state, but this is a matter of debate.

SCHEME 22.11 ODPM rearrangement with high degree of specificity.

SCHEME 22.12 Example for mixed mechanism of ODPM rearrangement.

22.6 Selectivity, Scope, and Limitations

Liao and coworkers⁴⁹ prepared bicyclo[2,2,2]octene derivatives (Scheme 22.13) with an aim to understand the intramolecular competition between ODPM, ADPM, and DPM rearrangements. Some of these substrates prepared by Liao displayed remarkable chemoselectivity toward ODPM rearrangement (Scheme 22.14), whereas only a few examples exist with high chemoselective ODPM rearrangement.^{50,51} The ODPM rearrangement reaction in these substrates is found to be dependent on the energy of triplet sensitizer, and acetophenone is found to be very effective. The observed selectivity is attributed to the stability of diradicals involved in ODPM rearrangement reaction.

The oximes **2a–2d** and exocyclicmethylene compounds **3a–3d** (Scheme 22.13) did not display ODPM rearrangement activity under triplet sensitization conditions and this may be due to free rotor effect leading to *E/Z* isomerization. The diastereo- and enantioselectivities in ODPM rearrangement reactions are reported by Ramamurthy and coworkers^{34,52–54} by confining the substrates in zeolite environment and also attaching chiral molecules to substrates. The preference of reactivity results from orientation of substrate and the proximity of the chiral attachment within the tight cage or rigid host molecule. Scheme 22.15 illustrates a few examples. The enhancement in the ODPM reaction is noticed when the substrates are confined to zeolites and also sensitized by triplet sensitizers (Scheme 22.16). Triplet sensitization is found to be very efficient within the zeolitic cages and this happens to improve the rearrangement product compared to solution-phase photolysis.³⁴

In another study, the ODPM rearrangement product found to exhibit polymorphism as determined by the x-ray diffraction data⁵⁵ (Scheme 22.17).

SCHEME 22.13 Chemoselectivity in ODPM rearrangement.

SCHEME 22.14 Regioselectivity in ODPM rearrangement.

SCHEME 22.15 Enantio- and diastereoselectivity in ODPM rearrangement.

Schaffner et al.^{56–58} studied the photochemistry of cyclic β,γ -unsaturated aldehydes (Scheme 22.18) and found that they underwent mainly decarbonylation reaction, although they can display ODPM rearrangement.

Another study by Dürr et al.⁵⁹ indicated that β,γ -unsaturated aldehydes (Scheme 22.19) exhibited decarbonylation and electrocyclization reactions and not ODPM rearrangement. Nevertheless, Schafner et al.⁶⁰ reported the first ODPM rearrangement reaction in β,γ -unsaturated (steroid-type) aldehyde (Scheme 22.20), along with decarbonylation and 1,3-acyl migration products.

SCHEME 22.20 First example of ODPM rearrangement in β,γ -unsaturated aldehydes.

SCHEME 22.21 Selected examples of ODPM rearrangement in β,γ -unsaturated aldehydes.

Later, Zimmerman also reported triplet reactivity of β,γ -unsaturated aldehyde showing ODPM rearrangement.⁶¹ Many people considered that these β,γ -unsaturated aldehydes are not good substrates for ODPM rearrangement, because of other competing photoreactions. Then Armesto group carried out many photochemical studies on β,γ -unsaturated aldehydes to prove that suitably designed and/or selected β,γ -unsaturated aldehydes can undergo efficient ODPM rearrangement with good selectivity and high efficiency. Some of the examples given in Scheme 22.21 indicate the efforts by Armesto group.⁶²

These results from Armesto group changed the earlier notion and proved that β,γ -unsaturated aldehydes can readily undergo ODPM rearrangement. The rationale given for the observed ODPM rearrangement activity in β,γ -unsaturated aldehydes is the selective population of triplet $\pi\pi^*$ state. The singlet and triplet $n\pi^*$ excited states may be responsible for decarbonylation reactions. The reactive state ordering and relative energy levels of singlet and triplet of $n\pi^*$ and singlet and triplet of $\pi\pi^*$ excited states in a given molecule may be directing the photoreactivity.

Cyclopentylmethyl ketones undergo ODPM rearrangement and as well as 1,3-acyl shift (Scheme 22.22) in solution phase.^{27,63,64} Gas phase photolysis of these cyclopentylmethyl ketones also produced products corresponding to ODPM rearrangement and 1,3-acyl shift. These studies indicate that there is a scope for conducting ODPM rearrangement in gas phase also to follow the mechanistic aspects.

van der Anton and Cerfontain⁶⁵ utilized several acyclic β,γ -unsaturated ketones to study ODPM rearrangement (Scheme 22.23). All these acyclic analogues primarily displayed *E/Z* (*cis-trans*) isomerization upon direct excitation or triplet sensitization. But, there were products related with ODPM rearrangement in small quantities. Further studies by Koppes and Cerfontain⁶⁶ on several β,γ -unsaturated ketones (Scheme 22.24) revealed interesting information. Cerfontain and coworkers^{65,66} studies revealed

SCHEME 22.22 ODPM rearrangement in gas phase.

SCHEME 22.23 β,γ -Unsaturated ketones that do not exhibit ODPM rearrangement.

SCHEME 22.24 Extra groups that reduce the ODPM activity.

that selective sensitization opened the way for ODPM rearrangement products, but direct photolysis provided mainly *E/Z* (*cis-trans*) isomerization with inefficient 1,3-acyl shift product. The substrates (Schemes 22.23 and 22.24) having γ,δ -double bond and also benzoyl group did not exert any influence on the photoreactivity. They have introduced a new hypothesis that charge-transfer interaction within the molecule enhances the internal conversion and this phenomenon reduces the ODPM activity.

Liao and coworkers⁶⁷ prepared various bicyclo[2.2.2]octadieneones to study their photochemical properties (Scheme 22.25) and these compounds are well-suited substrates for DPM and ODPM rearrangements. Direct excitation of **1a–e** (Scheme 22.25) in benzene, methanol, and acetonitrile gave only benzene derivative with extrusion of dimethylketene (Scheme 22.25). Interestingly, **1f** upon direct excitation provided benzene derivative (extrusion of dimethylketene) as a major product together with small amounts of rearranged products—tricyclic compounds (Scheme 22.25).

Compound **1a** upon acetone or acetophenone sensitization gave only benzene derivative as the main product (Scheme 22.25) and **1b–c** are unreactive. Compounds **1d–f** upon acetone sensitization gave small amounts of rearranged tricyclic products along with benzene derivative. Acetophenone was found to be an efficient sensitizer in producing higher amounts of rearranged tricyclic products (Scheme 22.25). The rearranged tricyclic products are the result of DPM rearrangement and there were no products related

SCHEME 22.25 Photochemistry of bicyclo[2.2.2]octadienones by direct and sensitized excitation.

with ODPM rearrangement. The authors provided extensive mechanistic considerations for the photochemical transformations studied. DPM rearrangement products and regioselectivities observed were believed to be due to stabilized diradical intermediates. These studies clearly indicate that there is a large scope to understand in detail the mechanistic aspects explaining product formation with selectivity.

22.7 Synthetic Potential

Banwell and coworkers⁶⁸⁻⁷⁰ reported the enantiomerically pure (–)-hirsutene (linear triquinanes) involving chemoenzymatic, Diels–Alder, and ODPM rearrangement reactions as key steps (Scheme 22.26) in their synthesis. The same key steps were utilized in the synthesis of (–)-compliatic acid and (+)-hirsutic acid.

Liao and coworkers⁷¹ reported the synthesis of (±)-magellanine (Scheme 22.27) using masked *o*-benzoquinone Diels–Alder protocol, via a triquinane intermediate involving ODPM rearrangement, intramolecular cyclization, selective oxidative cleavage, and double reductive amination as key steps.

SCHEME 22.26 Enantiomeric synthesis of (-)-hirsutene involving the ODPM route.

SCHEME 22.27 Synthesis of (±)-magellanine via ODPM rearrangement.

SCHEME 22.28 Synthesis of triquinane derivatives via ODPM protocol.

Bicyclo[2.2.2]octenones photochemistry served a lot in the synthesis of tricyclopentanoid compounds. Initially the ODPM rearrangement protocol was set by Demuth and Schafner¹⁵ and later it was Singh¹⁸ who conducted extensive studies. Diels-Alder reaction was utilized by Singh et al.⁷² to make extensive compounds of bicyclo[2.2.2]octenones and subjected them to ODPM rearrangement to make several triquinanes. These cycloadducts synthesized selectively underwent acetone-sensitized ODPM rearrangement, but did not undergo [2+2] cycloaddition reaction and not even 1,3-acyl migration sometimes. The bicyclo[2.2.2]octenone prepared from indanol derivative (Scheme 22.28) was photolyzed, under quartz envelope (254 nm) and also under acetone-sensitized conditions to get angular triquinane derivative.⁷³ Singh and coworkers have reported synthesis of bicyclo octenone and used them for ODPM rearrangement to complete the synthesis of several moieties and the same is described in the following.

(±)-Hirsutene was synthesized from a very simple starting material—salicyl alcohol via ODPM rearrangement. Salicyl alcohol was converted in to a tricyclic intermediate possessing β,γ -unsaturated ketone

SCHEME 22.29 Synthesis of (±)-hirsutene through ODPM rearrangement.

SCHEME 22.30 Synthesis of hirsutic acid and compliatic acid via ODPM route.

system (Scheme 22.29). Then it was photolyzed in acetone solvent to get tricyclopentanoid skeleton, which was readily converted into hirsutene.

Bicyclo[2.2.2]octenone derivatives have been synthesized and utilized in making (±)-hirsutic acid and compliatic acid via ODPM rearrangement (Scheme 22.30).^{74,75}

Scheme 22.31 explains the synthesis of tetraquinanes using indanol and also hydroxyl methyl tetrahydro naphthol as starting materials involving ODPM rearrangement reaction.⁷⁶

Liao and coworkers⁷⁷ developed a method to make bicycloctenone suitable for undergoing ODPM rearrangement and further leading to the natural product synthesis. They have used masked *o*-benzoquinone cycloaddition protocol to generate precursors to ODPM rearrangement (Scheme 22.32). These intermediates have a lot of potential in leading to several interesting molecules of interest.

Armesto group reported ODPM rearrangement in β,γ -unsaturated aldehydes (Scheme 22.33)⁶² where the products became significant as a possible intermediates leading to the synthesis of chrysanthemic acid (a pyrethroid) and its derivatives.

SCHEME 22.31 Synthesis of tetraquinane derivatives via ODPM rearrangement.

SCHEME 22.32 Synthesis of precursors to ODPM rearrangement.

SCHEME 22.33 Synthesis of pyrethroid derivatives via ODPM route.

SCHEME 22.34 Synthesis of modhephene via ODPM rearrangement.

The propellane-type terpene *modhephene* is another example of a complex natural product. The synthesis of modhephene involves first making of bicyclic-octenone derivative and followed by ODPM rearrangement. The resulting ODPM product served as key intermediate and was successfully converted to modhephene (Scheme 22.34).^{78,79}

Uyehara et al.⁸⁰ provided angularly annulated triquinanes by adopting ODPM route (Scheme 22.35). Indeed bicyclo[2.2.2]octenone derivative served as a precursor to ODPM rearrangement. Formation of third cyclopentane ring, after ODPM rearrangement, is an interesting aspect of the synthesis of angular triquinane.

A [4+2] cycloaddition, involving cyclohexadienone, methodology developed to make precursors to ODPM rearrangement⁸¹ and these precursors yielded tetracyclic products (Scheme 22.36). Other strained, ring enlarged, and benzannulated analogues were also introduced by this procedure (Scheme 22.36). The yields of ODPM route are found to be very good in these conversions.

SCHEME 22.35 Synthesis of angular triquinane derivative via ODPM rearrangement.

SCHEME 22.36 Synthesis of tetracyclic and benzannulated analogues via ODPM protocol.

SCHEME 22.37 Synthesis of bridged diquinanes through ODPM route.

SCHEME 22.38 ODPM rearrangement in enantiomers.

SCHEME 22.39 Synthesis of (-)-coriolin via ODPM rearrangement.

Another study, intramolecularly bridged bicyclo[2.2.2]octenone (the precursor to ODPM route), upon triplet sensitization leads to formation of bridged diquinanes⁸² (Scheme 22.37). An interesting photochemical reaction was also informed from the ODPM rearrangement product (Scheme 22.37).

The ultimate challenge for an efficient synthetic pathway to complex chiral target molecules is the generation of enantiomerically pure products either by use of enantiomerically pure starting materials or by application of asymmetric induction using prochiral substrates. The bicyclo[2.2.2]octenone is available in an enantiomerically pure form by a simple resolution procedure⁸³ from the racemic mixture involving the acetal diastereoisomers formed with tartaric acid (Scheme 22.38). Irradiation of the separated parent compound enantiomers under triplet sensitization conditions leads to diquinane in high enantiomeric purity. Another approach to enantiomerically pure ODPM substrates is described for bicyclo[2.2.1]heptenone.⁸⁴

This concept has been applied for the synthesis of the structurally complex and highly oxy-functionalized triquinane (-)-coriolin (Scheme 22.39).⁵⁰ Two carbonyl groups, both in the right position for 1,2-acyl shift, were present in the trimethyl functionalized bicyclo[2.2.2]octenone. The expected regioisomeric tricyclic dione was formed with high selectivity (Scheme 22.39). Subsequent chemical transformations provided the desired natural product coriolin.

22.8 Representative Experimental Procedures

22.8.1 Synthesis of Tricyclo[3.3.0.0.0]octane-3-One⁸³

A solution of 10 g of the β,γ -unsaturated bicyclic ketone (Scheme 22.40) in 1000 mL of acetone was purged with argon and irradiated in a water-cooled quartz vessel placed in a Rayonet RPR-208 photochemical reactor equipped with RUL ~ 3000 lamps ($\lambda \sim 300$ nm). Irradiation was continued for 72 h and

SCHEME 22.40 Synthesis of tricyclo[3.3.0.0.0]octane-3-one through ODPM route.

the reaction was monitored by TLC. After 72 h of irradiation, the conversion was $\sim 98\%$ and the only detectable compound was the ODPM rearrangement product, tricyclo[3.3.0.0.0]octane-3-one (Scheme 22.40). The solvent was distilled off and the residue was chromatographed over silica gel using a benzene/ether solvent mixture. The product, which was eluted (8.6 g), was further distilled under vacuum ($50^\circ\text{C}/1\text{ mm}$) to get the pure ODPM rearrangement product (tricyclic ketone) in 81% yield with 99.5% purity. The quantum efficiency determined was found to be $\phi = 1.0$.

22.8.2 Synthesis of 4,4,9,9-Tetramethyltetracyclo[6.4.0.0.0]dodecane-7,12-Dione⁸⁵

A solution of 1.25 g of 8,8,9,9-tetramethyl-1,3,4,6,7,8-hexahydro-1,4-ethanonaphthalene-2,5-dione (a δ -oxo- β,γ -unsaturated ketone; Scheme 22.41) in 300 mL cyclohexane was degassed by bubbling nitrogen through the solution and was irradiated for 3 h in Rayonet photochemical reactor ($\lambda \sim 300\text{ nm}$). The reaction was monitored by TLC and only one product was detectable. Evaporation of the solvent and recrystallization of the crude photolysate afforded the ODPM rearrangement product in 78% yield. The quantum yield of the reaction was determined as $\phi = 0.67$. Solvents like acetonitrile, benzene, or acetone and sensitizers like acetone or xanthone, respectively, can be employed for this reaction without altering the yield of the ODPM rearrangement product.

22.8.3 Synthesis Fluorenylcyclopropane Derivative⁶²

A solution of 3-(9H-fluoren-9-ylidene)-2,2-dimethylpropanal (400 mg, 1.6 mmol) and *m*-methoxyacetophenone (10 g, 66 mmol) in dry dichloromethane (420 mL) was purged for 1 h with argon and irradiated for 2 h with a Pyrex filter and a 400 W medium-pressure Hg arc lamp. After completion of the irradiation, the solvent was removed under reduced pressure, and the products were separated by flash chromatography using hexane/Et₂O (9:1) as eluent on silica gel gave 385 mg (96%) of cyclopropyl aldehyde as colorless oil (Scheme 22.42).

SCHEME 22.41 Synthesis of 4,4,9,9-tetramethyl tetracyclo [6.4.0.0.0] dodecane-7,12-dione via ODPM route.

SCHEME 22.42 Synthesis of cyclopropenyl fluorenyl derivative through ODPM route.

22.9 Target Molecules for ODPM Rearrangement Studies

There are several molecules mentioned as target molecules for the possible study of ODPM rearrangement. The future will definitely have many applications toward the ODPM activity. The small molecules will be more interesting to study, because of the recent findings on the nature and energy of the triplet sensitizer-dependent ODPM activity.

Acknowledgments

V. Jayathirtha Rao thanks DST, New Delhi, for financial support and Director, IICT, for encouragement. K. Srinivas thanks Project Director, NIPER-Hyderabad, for encouragement. The authors thank Dr. K. Bhanuprakash, IICT, for fruitful discussions.

23.1 Cycloaromatization Reactions: Introduction

Naturally occurring enediyne antibiotics¹ are often hailed as the most potent family of anticancer agents discovered to date.² These molecules were developed by microorganisms as the most powerful chemical warfare targeting cellular DNA with astounding efficiency. The key step in the chemical mechanism responsible for this activity is the transformation of the enediyne moiety to a reactive *p*-didehydrobenzene diradical (*p*-benzyne). This step, the simplest version of which is given in Scheme 23.1, is a cycloaromatization reaction called the Bergman cyclization.³ The simultaneous formation of two radical centers is important because it results in the abstraction of two hydrogen atoms (one from each strand of a double-stranded (ds) DNA), which, after a sequence of reactions, ultimately leads to ds DNA cleavage.⁴

SCHEME 23.1 The four cyclizations of (Z)-hex-3-ene-1,5-diyne (a, b) and (Z)-hept-3,5,6-triene-1-yne (c, d). (From Alabugin, I.V. et al., *Adv. Phys. Org. Chem.*, 42, 1, 2007. With permission.)

While cycloaromatization reactions came to the forefront of active research after the discovery of the remarkable biological activity of natural enediynes, these processes present unique challenges from the fundamental perspective as well. A characteristic feature of cycloaromatization reactions is that one σ -bond is formed in the cyclization step at the expense of two in-plane π -bonds. When the two π -bonds are transformed into a σ -bond and a pair of radical centers, the process leads to a net loss of one chemical bond and, thus, should be strongly disfavored thermodynamically. However, the overall energy penalty for this seemingly unfavorable process is lower than that in the analogous cyclizations of alkenes.⁵ For example, ΔH for the cycloaromatization process of the parent enediyne **1** into a *p*-benzyne diradical^{3b} (the Bergman cyclization, Scheme 23.1) is only 8–9 kcal/mol.⁶ Such a low value is explained by the stabilization of the product provided by the aromatic system created at the expense of the out-of-plane π -orbitals of the parent system. Developing aromatic stabilization in the conjugated out-of-plane system plays an important role in deepening the potential energy well for the diradical product to the extent where this species can be trapped by external reactions.

Scheme 23.1 summarizes the possible cyclizations involving the prototype enediyne (Z)-hex-3-ene-1,5-diyne (the Bergman and Schreiner–Pascal cyclizations) and the prototype ene-yneallene (Z)-hept-3,5,6-triene-1-yne (the Schmittel and Myers–Saito cyclizations). In all of these processes, diradical species and new bonds are formed at the expense of the in-plane π -orbitals in the presence of an orthogonal π -system. However, the properties of the newly formed cyclic conjugated systems and the thermodynamic driving force for these reactions are quite different. In the ground state, an aromatic system is formed only in the Bergman and Myers–Saito cyclizations, and thus, in a sense, only these two processes are true cycloaromatization reactions. The Schreiner–Pascal⁷ and Schmittel⁸ cyclizations do not have the beneficial effect of the formation of an aromatic system. Consequently, these reactions are much more endothermic than the Bergman and the Myers–Saito cyclizations in the ground state. However, the situation can be changed by addition of electrons, as illustrated by the significantly more efficient reductive C1–C5 cyclizations of enediynes where, unlike the fulvene product of the thermal closure, the anionic product possesses some of the aromatic character of cyclopentadienyl anion.⁹

This chapter will be selective in coverage since a number of reviews are already available on various aspects of the enediyne chemistry and biochemical applications of cycloaromatization reactions. For example, Rawat and Zaleski¹⁰ discussed geometric and electronic control of thermal Bergman cyclizations, while Basak and coworkers¹¹ described the use of enediynyl ligands in chelation-controlled Bergman cyclizations. König and coworkers¹² provided a review of electronic effects in the Bergman cyclization. Alabugin and Breiner dissected the relative importance of the two π -systems at different

stages of cycloaromatization processes.¹³ Schreiner scrutinized computational approaches to studies of cycloaromatization reactions.¹⁴ The early development of photochemical Bergman cyclization has been reviewed by Jones and Russell.¹⁵ Basak and coworkers¹⁶ compared different approaches to selective activation of enediyne prodrugs including photo- and pH-activation. These comprehensive reviews give us an opportunity to be selective in the choice of material and focus on the newer findings, while limiting ourselves to only those examples that illustrate the key trends in the cyclization efficiency.

23.2 Photochemical Reactions of Enediynes

23.2.1 Impetus for the Development of Photochemical Bergman Cyclizations

Despite their highly elaborate architecture and high activity, natural enediynes do not differentiate between healthy cells and cancer cells and, thus, are extremely toxic. Such lack of selectivity toward cancer cells is the greatest problem that prevents enediyne antibiotics from achieving their full potential as anticancer drugs. Numerous attempts to achieve higher spatial and temporal control over reactivity have produced a lot of research into the synthesis of analogues of the naturally occurring enediynes.^{17,18} This includes attempts to tune the reactivity of designed enediynes through either strain^{19–21} or electronic^{22,23} effects, and most recently, to conjugate natural enediynes with monoclonal antibodies.²⁴ The challenge is that these compounds have to be relatively stable to allow handling at ambient temperatures but need to become activated at body temperature for attack upon DNA. Unless a special triggering event is used to convert a prodrug to its active form, there is only a narrow temperature/time window where reactivity and stability are balanced for thermally activated enediynes.

All of the aforementioned points explain why the ever-increasing efforts have concentrated on selective activation of enediynes by light.^{25–32} The use of tissue-penetrating light allows for efficient spatial and temporal control over prodrug activation because light can be delivered directly at the tumor at the right time when it contains high concentration of the drug. This advantage is illustrated by the emergence of photodynamic therapy (PDT) as a powerful and convenient alternative to traditional cancer therapy methods.

23.2.2 Experimental Studies of Photochemical Bergman Cyclization

Although Bergman himself found that no photochemical cyclization is observed during irradiation of the parent enediyne,³ a photochemical transformation that can be classified as a photo-Bergman reaction was reported as early as 1968 by Campbell and Eglinton (Scheme 23.2).³³ The substituted naphthalene structures of the products were assigned on the basis of mass-spectral analysis and their conversion to naphthalene upon hydrogenolysis. The yields for the cyclic products were low, most likely due to the lack of suitable H-donor in these experiments.

Since the early examples were discouraging, it took about 25 years and the discovery of anticancer enediyne antibiotics for the idea of photochemical triggering of the Bergman cyclization to reemerge as the focus of active scientific pursuit. The first attempt to use enediynes for photochemical DNA cleavage

SCHEME 23.2 First report of photochemical Bergman cyclization.

SCHEME 23.3 Photochemical Bergman cyclization of aromatic enediynes. (From Evenzahav, A. et al., *J. Am. Chem. Soc.*, 120, 1835, 1998. With permission.)

was reported by Kagan et al. in 1993.²⁵ However, irradiation of 1,6-diphenyl-3-hexene-1,5-diyne in THF did not yield any of the expected product of the Bergman cyclization, *o*-terphenyl. Instead, the enediyne underwent *cis*–*trans* bond isomerization along with formation of a minor amount of polymer product. This disappointing result notwithstanding, the authors found that the same enediyne causes extensive single-stranded (ss) DNA photocleavage in supercoiled pBR322 DNA. The origin of the photodamage still remains unclear until a recent report disclosed that efficient DNA cleavage can be achieved by monoalkynes incapable of the Bergman cyclization.³⁴

In 1994, Turro et al. reported that the photochemical Bergman cyclization becomes more efficient once the central bond isomerization is prevented through incorporation of this bond into a ring (Scheme 23.3).²⁶ Although photochemical alkyne reduction remained a major reaction pathway and the yield of the cyclized product was rather low (24% in isopropanol), the result was conceptually very important and encouraged a number of subsequent studies.

Evenzahav and Turro,^{26b} also reported that the photo-Bergman cyclization can proceed when the terminal propyl groups in enediyne **2** are replaced by phenyl groups (Scheme 23.4, top). Literature data for the photochemical reactivity of this specific molecule are mixed. More recent reports suggest that, despite the high (~75%) conversion, the yield of the naphthalene products is low (<10%,³⁵ ~1%³⁶). Interestingly, Ramkumar et al. reported formation of fulvene products from the same enediyne under oxidative electron transfer conditions (Scheme 23.4, bottom).^{31f,37}

In 2000, Jones et al. found that several cycloalkene diynes **3** with the analogous 1,6-diphenyl substitution underwent the photochemical Bergman cyclization in slightly higher yields but the respective cyclopentene diyne was not reactive at all (Scheme 23.5, top).²⁷ A monophenyl substituted cyclohexene enediyne **3b** gives even lower yield (<10%) of the cyclized product than the diphenyl-substituted cyclohexene diyne **3a**. Interestingly, when the enediyne part is coupled with a moderately bulky group attached at the *meta*-position through an alkyne linker in **3c**, the photochemical Bergman cyclization becomes quite efficient (44%). No explanation of such different reactivity has been provided so far.

Poor photoreactivity of cyclopentene diynes was also reported by Kaneko et al.²⁸ (Scheme 23.5, bottom) who found that only dimethyl substituted enediyne **4d** was reactive even under harsh irradiation conditions (254 nm). None of the substrates was reactive under Pyrex-filtered light. The latter result is

SCHEME 23.4 Photochemical transformations of 1,2-bis(2-phenylethynyl)benzene. (From Evenzahav, A. et al., *J. Am. Chem. Soc.*, 120, 1835, 1998. With permission.)

SCHEME 23.5 Photoreactivity of cycloalkene diynes. (From Kaneko, T. et al., *Angew. Chem. Int. Ed. Engl.*, 38, 1267, 1999. With permission.)

not surprising because enediynes without terminal aryl substituents do not absorb above 280–310 nm. No explanation for the remarkable effect of the two methyl substituents has been offered to date.

A very interesting observation by Spence and coworkers³⁵ is that 1-ethynyl-2-phenylethynylbenzene requires shorter irradiation times and affords higher yields of the photo-Bergman cyclization product than 1,2-bis(2-phenylethynyl)benzene (Scheme 23.6). This is an opposite trend in comparison to that for compounds **3a** and **3b** in Scheme 23.5.

When the acetylenic termini are included in a 10-membered ring as in cyclodec-3-ene-1,5-diyne, the formation of *p*-benzyne intermediate proceeds in high yield (Scheme 23.7).²⁸ However, the rate of

SCHEME 23.6 Photoreactivity of 1-ethynyl-2-phenylethynylbenzene. (From Spence, J.D. et al., *Tetrahedron Lett.*, 48, 725, 2007. With permission.)

SCHEME 23.7 Competition between photo-Bergman cyclization and retro-Bergman cleavage in the photochemistry of cyclodec-3-ene-1,5-diyne. (From Kaneko, T. et al., *Angew. Chem. Int. Ed. Engl.*, 38, 1267, 1999. With permission.)

hydrogen abstraction by the intermediate 1,4-diradical is apparently slower than the rate of the retro-Bergman opening leading to the formation of 1,2-ethynylcyclohexene. The overall transformation can be considered as a strain-driven photo-Cope rearrangement. This result suggests that the ratio of products is likely to depend on the nature and concentration of the hydrogen donor. Indeed, although the hydrogen donor concentration effects were not studied, the product ratio was found to differ from solvent to solvent.

The aforementioned results are consistent with observations of Funk et al.²⁹ who found that strained, cyclic enediyne annealed to a polycyclic aromatic core undergo especially facile photochemical Bergman cyclization while related terminal acetylenic compounds such as 4,5-diethynylpyrene are unreactive. Obviously, the retro-Bergman cleavage in this case is possible only in the direction of the starting material and no isomerization is expected, unlike the case of cyclodecenediyne. However, the fact that the cyclization in Scheme 23.8 proceeds more slowly with less than 30 equivalents of 1,4-cyclohexadiene (1,4-CHD) suggests that the cyclization is reversible and that the retro-Bergman ring cleavage may provide a more efficient pathway for diradical deactivation than hydrogen abstraction. This notion is further confirmed by the contrasting reactivity of two naphthalene-fused enediyne—only the formation of a more thermodynamically stable phenanthrene cycle is observed.

Peterson et al. reported the photochemical reactivity of imidazole-fused cyclic enediyne.³⁸ Irradiation of degassed enediyne solutions with 450 W low-pressure Hg lamp with a quartz filter gave benzimidazole derivatives in yields that were dependent on the nature of solvent and the substituents at the alkyne termini (Scheme 23.9). The cycloaromatized product was obtained in the highest yields (26%–64%) for R = Ph, with the best yield obtained using THF as solvent. Yields for the two alkyl substituted enediyne (R = Me and Bu) depend very strongly on the solvent. The relatively low yields for R = Me contrast the 75% reported for an analogous enediyne with a benzene core (Scheme 23.5, bottom). The cyclic enediyne yielded 45% of cycloaromatized product upon irradiation, even though related 11-membered ring enediyne were shown to be thermally unreactive.³⁹

Russell and coworkers reported thermal and photochemical cyclizations of cyclic pyrimidine enediyne and enediynone (Scheme 23.10).³⁰ Again, the cyclic structure favors the cyclization and irradiation of the alcohol and provides 83% of the cyclized product. On the other hand, irradiation of the corresponding ketone leads to a complex mixture with only 10% of cyclized products. No solvent or hydrogen donor concentration effects were studied.

Branda and coworkers provided another example of a cyclic enediyne that undergoes a photochemical reaction different from a photo-Bergman ring closure.⁴⁰ This group reported the elegant design of a cyclic photochromic enediyne that undergoes hexatriene electrocyclization when activated with 365 nm light. The cyclized compound can be reopened with >525 nm light. Interestingly, photochemical

SCHEME 23.11 Competition of photo-Bergman ring closure with hexatriene electrocyclic cyclization in photochromic enediynes. (From Sud, D. et al., *Angew. Chem. Int. Ed.*, 46, 8017, 2007. With permission.)

Bergman cyclization was not observed (Scheme 23.11) suggesting that the electrocyclic ring closure is much faster.

The complex effect of the chromophore nature on the enediyne reactivity was further illustrated by Alabugin and Kovalenko, who found that an increase in the electron acceptor ability of the chromophore⁹ changes the direction of the cyclization path. When tetrafluoropyridyl (TFP) groups were attached to the enediyne moiety (Scheme 23.12, top)^{9a}, cyclization proceeded with the formation of indenenes instead of the naphthalene products of the Bergman cyclization. When the core chromophore is changed to pyrazine (Scheme 23.12, bottom), interaction of enediyne moiety with 1,4-cyclohexadiene proceeds to a cycloadduct.⁴¹ The latter change in reactivity is attributed to the particularly fast formation of an electrophilic triplet state, which attacks the π -bond of 1,4-CHD.

The radical-anionic C₁–C₅ cyclization of enediynes represents a new type of cycloaromatization reaction—the “cycloaromatization” process driven by rearomatization in the vicinity of the transition state (TS).^{9b} Experimental work unambiguously established photoinduced electron transfer (PET) as

SCHEME 23.12 New photochemical reactions of enediynes promoted by variations at the core and terminus of the enediyne moiety. (From Alabugin, I.V. et. al., *J. Am. Chem. Soc.*, 124, 9052, 2002. With permission.)

SCHEME 23.13 Photochemically induced reductive C1–C5 cyclization of enediynes. (From Alabugin, I.V. et al., *J. Am. Chem. Soc.*, 124, 9052, 2002. With permission.)

the triggering event for the C1–C5 cascade and the intermediacy of the second PET step in the indene-forming cascade. Unlike the stable benzene product of the Bergman cycloaromatization, the fulvene intermediate of C1–C5 cyclization (prepared independently through Bu_3Sn radical mediated 5-exo-cyclization of enediynes)^{42,43} is capable of further photoreduction to indenenes with abstraction of two additional hydrogen atoms from the environment (Scheme 23.13). Due to this feature, C₁–C₅ cyclizations are interesting from the medicinal perspective, because incorporation of four rather than two hydrogen atoms from the environment as the result of the cycloaromatization cascade increases the DNA-damaging potential of the enediyne “warheads.”^{9a} Indeed, TFP-enediynes equipped with DNA-recognition elements have been shown to be capable of inducing 100–1000 times more ds DNA cleavage than expected from a combination of random coincident ss cleavages.⁴⁴

An interesting example of a five-membered ring formation related to the photo-Bergman cyclization has been reported by the Matzger group.⁴⁵ Photochemical activation of bis-(phenylethynyl) sulfide in hexane in the presence of 1,4-CHD produced 3,4-diphenyl-thiophene through the presumed intermediacy of the 2,5-didehydrothiophene diradical (Scheme 23.14). The thermal version

SCHEME 23.14 Photochemical transformation of bis-(phenylethynyl) sulfide in 3,4-diphenyl-thiophene. (From Lewis, K.D. et al., *Org. Lett.*, 5, 2195, 2003. With permission.)

of this process is also known and constitutes the first example of a cycloaromatization reaction exploiting the aromaticity of a heterocyclic ring.

23.2.2.1 Summary of Experimental Trends

The experimental evidence indicates that incorporating an enediyne in a strained ring favors the photochemical Bergman cyclization. However, the same evidence also shows that the cyclic structure makes the cyclization step reversible through the retro-Bergman cleavage. As a consequence, the diradical may undergo many cyclization/ring opening (Bergman/retro-Bergman) cycles before it actually abstracts a hydrogen atom from a hydrogen donor. Unfortunately, no photochemical quantum yields for the photochemical Bergman cyclization of a cyclic enediyne have been determined and the role of the retro-Bergman deactivation pathway remains unexplored.

Unlike the cyclic structure, the terminal Ph substitution is not consistently efficient. For example, it fails to promote the photochemical Bergman cyclization of cyclopentenediynes and is only moderately effective in the other cases (Scheme 23.5). Also, it is not clear why the introduction of a *meta* substituent into a terminal aryl group on the enediyne has such a large positive effect.

The effect of methyl substitution at the acetylene terminus on the cyclization efficiency is mixed as well. However, with just a limited number of known examples, there is not enough data to understand the reasons for this inconsistency, especially because the analogous propyl substitution in benzan-related enediynes does not lead to an efficient cyclization³⁸ whereas butyl substitution in an imidazole-fused enediyne favors the cyclization more than methyl substitution. More detailed studies are required.

To complicate the matter even further, electronic excitation enables additional reaction pathways different from the Bergman cyclization such as *cis-trans* isomerization, photoreduction, C1–C5 cyclization, and photocycloadditions. Since some of these reactions are not cycloaromatization processes, we need to discuss briefly the relevant photochemistry of bis-alkynes and related enynes.

23.2.3 Relation between Photo-Bergman Cyclization and Other Photochemical Reactions of Alkynes: Photo-Bergman Cyclization as Interrupted [2 + 2] Cycloaddition

Changes in the in-plane π -orbitals during the Bergman ring closure are analogous to the first step of an asynchronous [2 + 2] cycloaddition (Figure 23.1). The main difference is that the cyclobutene formation, which is the usual escape route for the 1,4-diradical intermediate, is impossible due the geometric restrictions imposed by the cyclic framework. Additional stabilization of the intermediate by its aromatic out-of-plane π -system further facilitates formation of this species. An alternative regioselectivity of the σ -bond formation would lead to the formation of a similar 1,4-diradical but in a five-membered

FIGURE 23.1 Comparison of Bergman and C1–C5 cyclizations with interrupted [2 + 2] cycloadditions.

SCHEME 23.15 Photorearrangement of enynes. (From Zheng, M. et al., *J. Am. Chem. Soc.*, 115, 12167, 1993. With permission.)

ring, which is not stabilized by aromaticity in the ground state but possesses aromaticity in some of the excited states.⁴⁶

In accord with this analysis, even when no aromatic system is formed, photochemical processes topologically similar to the photo-Bergman cyclization are still possible. A remarkable example is provided by the photorearrangement of acyclic conjugated enynes reported by Johnson and coworkers⁴⁷ (Scheme 23.15). This transformation is consistent with enyne photocyclization to highly strained 1,2-cyclobutadienes through singlet excited state formation and subsequent thermal ring opening. The overall photoinduced equilibrium bears striking topological resemblance to the Bergman cyclization coupled with the retro-Bergman ring opening (Scheme 23.7).

A classic example of a photochemical process that follows [Figure 23.1](#) and does not provide an aromatic product is the photochemical cyclization of diethynylmethanes, discovered by Zimmerman and Pincock⁴⁸ around the time that Bergman reported enediyne cyclization. The reaction (Scheme 23.16) can proceed upon direct excitation of a nonconjugated 1,4-diyne in isopropyl alcohol or upon triplet sensitization by acetophenone or xanthone. A moderately high quantum yield (0.25) upon sensitization with acetophenone indicates a relatively efficient triplet reaction.

A similar photocyclization of a conjugated triaryl "Y-enyne" has been reported by Kaafarani and Neckers (Scheme 23.17).⁴⁹ Unlike the previous example, the cyclization proceeds at a pendant aromatic ring. A related nonphotochemical reductive cyclization involves both triple bonds and leads to the formation of a five-membered ring.⁵⁰

Schmitt et al. illustrated the potentially broader scope of photochemical cycloaromatization reactions in their report of triplet photochemical reactions of enyne-carbodiimides and enyne-ketenimines (Scheme 23.18).⁵¹ Photolysis of degassed solutions of substituted enyne-carbodiimides led to the formation of indoloquinolines. When the enyne-carbodiimides are substituted by an electron-withdrawing group either at the alkyne or at the carbodiimide termini, direct irradiation at 300 nm or longer wavelengths proceeds as an efficient (>90%) and highly regioselective 5-*exo*-dig closure. The cyclization is suggested to take place via triplet heterobenzofulvene biradical intermediates. The photochemical cyclization in toluene and *n*-hexane could be completely suppressed in the presence of 1,4-diphenyl-1,3-butadiene, a triplet quencher with $E_T = 42$ kcal/mol. The photocyclization of enyne-ketenimines under the same reaction conditions resulted in slightly lower yields due to formation of a polymeric material.

The above data illustrate the multichannel nature of alkyne/enediyne photoreactivity and reiterate the importance of a basic understanding of the factors controlling the nature of excitation in the enediyne system. A robust theoretical model that incorporates the disjointed experimental data in a coherent and logical framework is crucial for explaining the aforementioned experimental observations

and guiding the future development of this field. The following section provides such a framework by discussing electronic changes that accompany the cycloaromatization process and how these changes are related to photochemical activation.

23.3 MO Analysis of Cycloaromatization Reactions

The relative contributions of the two orthogonal π -systems, which are important for the understanding of electronic factors in the thermal Bergman cyclization, become even more relevant in the photochemical processes. Not only can the substituent effects on the cyclization originate from the two sources (in-plane and out-of-plane MOs) but the two orbital arrays may also be directly involved in the excitation processes, potentially providing different electronically excited states, each with unique

FIGURE 23.2 VB curve crossing diagram showing the crossing between the valence bond configurations involving in-plane bonds and orbitals in the reactant and product of the Bergman cyclization, $\Phi_{\sigma R}$ and $\Phi_{\sigma P}$.⁵² Actual surface after mixing is shown as the continuous curve connecting $\Phi_{\sigma R}$ of enediyne with $\Phi_{\sigma P}$ of *p*-benzyne. Energies are in kcal/mol relative to the ground state of the parent enediyne at the σ -1-VB-DFT level. A—thermal Bergman cyclization, B + C—photochemical route to the same TS. (From Galbraith, J.M. et al., *Chem. Eur. J.*, 6, 1446, 2000. With permission.)

reactivity. Communication between the two orthogonal π -systems can lead to an interconversion of different excited states and drive chemical reactivity in directions that are difficult to achieve in a purely thermal process.^{9b} As a result, the relative roles of the two π -arrays becomes crucial and warrant the detailed analysis provided in this section.

Galbraith et al.⁵² utilized VB theory to gain insight into the structural and electronic nature of the transition state and the role of the σ - and π -frameworks in thermal Bergman cyclization. The dominant VB configuration of the enediyne reactant, $\Phi_{\sigma R}$, plays only a minor role in the *p*-benzyne diradical, while the dominant VB configuration in the biradical product, $\Phi_{\sigma P}$, is insignificant in the starting material (Figure 23.2). The avoided crossing of the energy curves corresponding to these two VB configurations (or electronic states corresponding to these configurations) corresponds to the transition state. This analysis is useful for the design of the photochemical Bergman cyclization because it clearly illustrates that both the position and the energy of the TS depend on the ground and excited state energy surfaces. A particularly relevant corollary of this analysis is that the state crossing (the TS) can be reached starting either with the ground state or from a suitable excited state and that, in the latter case, the cyclization should be much more energetically favorable.

The main challenge in achieving the aforementioned transformation efficiently is in finding a way to reach the correct excited state surface selectively and in directing the distribution of excitation energy in a productive way through appropriate molecular design. Since both π -systems are involved in the cycloaromatization process, clear dissection of their respective roles is important for the analysis of reactivity. Alabugin and Manoharan illustrated how these challenges can be tackled via the analysis of MO correlation diagrams.^{53,9b} In this analysis, monitoring the cyclization process at the level of individual MOs enables detailed understanding of electronic reorganization along the reaction coordinate (Scheme 23.19). The most important changes at the TS stage are the dramatic increase in the energy of HOMO-1 and the decrease in the energy of LUMO + 1, which occur due to the transformation of the enediyne in-plane π - and π^* -orbitals (bonding and antibonding, respectively) into the nonbonding MOs (radical centers) of the diradical (Scheme 23.19, left). Destabilization of the HOMO-1 is the greatest energy penalty for the enediyne to reach the Bergman cyclization TS. This effect is partially offset by a

SCHEME 23.19 Left: Partial MO diagram that illustrates the frontier MO (FMO) changes in the process of thermal Bergman cycloaromatization. Center: Analogous changes for a hypothetical photochemical Bergman cyclization promoted by excitation, which involved the *in-plane* FMOs. This reaction should be more favorable than the ground state Bergman cyclization. Right: Even more potentially favorable adiabatic photochemical Bergman cyclization from a higher excited state. (From Poluokhtine, A. et al., *J. Org. Chem.*, 71, 7417, 2006. With permission.)

FIGURE 23.3 The key molecular orbitals of *o*-diethynylbenzene.

σ -bond forming interaction that stabilizes HOMO-2 (not shown, the in-phase combination of the in-plane enediyne π -orbitals). Developing aromatic stabilization of the out-of-plane π -system lags behind the aforementioned changes but becomes progressively more and more important as the reaction coordinate approaches the *p*-benzyne product.⁵⁴

The key MOs of the parent benzannelated enediyne, *o*-diethynylbenzene, are shown in Figure 23.3. They are analogous to the MOs of the parent enediyne and, thus, the main points of the aforementioned analysis are applicable to benzannelated enediynes as well.

23.3.1 MO Analysis of Photochemical Bergman Cyclization

23.3.1.1 Allowed Photo-Bergman Cyclizations

The MO correlation diagram illustrates that the thermal Bergman cyclization is a symmetry-allowed process (Scheme 23.19, left) because the antisymmetric combination of the nonbonding (radical) orbitals is lowered in energy relative to the symmetric combination by through-bond (TB) interaction between the two radical centers.⁵⁵

An adiabatic photochemical Bergman cyclization should also be a symmetry-allowed process as long as it involves excitation of the in-plane orbitals (Scheme 23.19, center and right). Moreover, inspection of

the in-plane orbitals suggests that promotion of an electron from the highest occupied in-plane orbital, which is antibonding between the end atoms of the enediyne system, to the lowest unoccupied in-plane orbital, which is bonding between the same atoms, should greatly facilitate the cyclization. These in-plane MOs correspond to HOMO-1 and LUMO + 1 in the parent enediyne.

However, excitation of the “frontier” in-plane orbitals does not correspond to the lowest energy excited state in simple enedynes* and, according to the Kasha’s rules,⁵⁶ is unlikely to manifest itself directly in the observed photochemical reactivity. Does it mean that the photo-Bergman cyclization is destined to be an inefficient process? In the next section, we will discuss how this limitation can be overcome.

23.3.1.2 Orbital Crossings in “Forbidden” Photo-Bergman Cyclizations

The photo-Bergman cyclization from the lowest excited state corresponding, in the first approximation to a HOMO–LUMO transition between the out-of-plane MOs, can be formally classified as a symmetry-forbidden process because electronic states of the reactant and the product are different. As the result, the reaction has to suffer from an additional energy penalty needed to reach the orbital crossing that interconverts the two states (Figure 23.4). In this scenario, the crossing point should control the energy to the transition state for the photochemical Bergman cyclization.

Two points are especially important in this analysis. First, unlike the usual ground state reactions where the additional energy penalty due to the “forbiddenness” is substantial as the result of the large energy difference between the crossing states (the ground state and an excited state), this penalty is not prohibitive for the crossing between the two excited states because the energy difference between the

FIGURE 23.4 Comparison of FMO correlation diagrams for two adiabatic photochemical Bergman cyclizations. *Left:* Excitation involves the in-plane MOs and the cyclization is allowed. *Right:* The excitation involves the out-of-plane MOs and the process has an additional penalty ΔE imposed by the MO crossing between the lowest excited states of reactant and the product (an analogous crossing and analogous energy penalty would be observed for a diabatic photocyclization, which forms the ground state of the product).

* The difference in the excitation energy of the *out-of-plane* and *in-plane* orbitals is expected to be close in magnitude to the difference between the energy of $\pi \rightarrow \pi^*$ absorptions in hexatriene and ethylene.

two excited states is usually smaller than the difference between the ground and excited states. Second, the TS energy depends on both the out-of-plane (initially populated) MO and the in-plane (populated after crossing) MO and the overall reaction barrier can be controlled through a rather interesting interplay of electronic effects, which include both of the two orthogonal π -arrays. In short, the TS energy for this class of photochemical Bergman cyclizations can be decreased by either destabilizing the out-of-plane MO (usually the LUMO) or by stabilizing the in-plane MO (LUMO + 1, [Figure 23.4](#)).

An additional consideration is that electronic coupling between the crossing states will result in an avoided crossing, which lowers the observed barrier. Such coupling would depend on the efficiency of interaction between the two initially orthogonal π -arrays and would be facilitated through deviations from planarity, which lowers the initial symmetry.⁹

The general MO analysis discussed earlier explains why no photochemical cyclization has been observed during irradiation of the enediyne **1** at the room temperature⁷ and why such side reactions as *cis-trans* isomerization²⁵ and photoreduction²⁶ are observed instead in related compounds. In those cases, the lowest excited state does not involve the in-plane orbitals directly involved in the cyclization. Instead, the lowest excited state involves transitions with participation of only the out-of-plane π -orbitals that mostly correspond to the enediyne HOMO and LUMO.

This general analysis agrees well with UDFT and MCSCF calculations of the photochemical Bergman cyclization of enediynes by Clark et al.⁵⁷ who computed the three lowest singlet and triplet vertical excited states of the parent enediyne, *cis*-hex-1,5-diyne-3-ene as well as several of the respective potential energy surfaces for its Bergman cyclization. Despite the high exothermicity (−42 kcal/mol at the CASMP2 level), Bergman cyclization along the a^3B path was found to be unfavorable due to the competition with *cis-trans* isomerization at the central bond and H-abstraction at the terminal alkyne carbons. Singlet photoexcitation to an alkyne-localized excited π - π^* state was more efficient in promoting an in-plane geometric distortion leading to the Bergman diradical.

In summary, for the successful design of the photochemical Bergman cyclization one needs to decrease the energy of the in-plane absorption. It is not clear at this point whether such decrease can be sufficiently large to achieve the allowed photo-Bergman cyclizations described in the previous sections. However, even if the “in-plane” excited state remains higher in energy than the “out-of-plane” excited state, the “in-plane” state energy lowering will result in a parallel lowering of the crossing between the two states and, as discussed earlier, decrease in the activation barrier for the cyclization. As the result, even forbidden photo-Bergman cyclizations should still be facilitated by the “in-plane excited state” stabilization.

One can see that control of photo-Bergman cyclizations requires a detailed understanding of the nature of photochemical excitation.⁵⁸ Generally, this task is not a trivial undertaking, especially when considering the highly delocalized and multiconfigurational nature of the excited states. However, analysis of molecular orbitals involved in the excitation reveals several promising approaches that not only rationalize the available experimental data from the multiple literature sources but also suggest new ideas that can be tested experimentally. In order to understand the logic of these approaches, it is illustrative to consider the energy gap between the LUMO and LUMO + 1 of the enediyne moiety. If the gap is decreased, the excitation energy should decrease as well and, at some point, it may become possible to deliver the excitation to the in-plane MO manifold. Several ways to decrease this gap are discussed in the following.

23.3.2 Factors Controlling Photo-Bergman Cyclizations

23.3.2.1 Strain

The first way to decrease the gap is to include the enediyne moiety in a strained cycle where the terminal enediyne carbons are brought closer.²⁰ This change should destabilize the HOMO-1 where the interaction between the end orbitals is antibonding and stabilize the LUMO + 1 where the π^* -orbitals overlap constructively as shown in [Figure 23.5](#).

This model offers an interesting attenuation of the concept of strain control in enediyne reactivity by Nicolaou et al.¹⁹ who had argued that the increase of strain promotes the Bergman cyclization by the

FIGURE 23.5 Comparison of the in-plane FMO gap between the in acyclic (left) and cyclic (right) enediynes. Incorporation of the enediyne moiety into a cyclic structure simultaneously increases the energy of the HOMO-1 and lowers the energy of the LUMO + 1. In this example, the central part of the enediyne moiety is included into a benzene ring to prevent the retro-Bergman opening into an acyclic product. (From Alabugin, I.V. et al., *J. Phys. Chem. A*, 107, 3363, 2003. With permission.)

SCHEME 23.20 Synthesis of reactive enediynes via photochemical ring contraction. (From Karpov, G.V. et al., *J. Am. Chem. Soc.*, 129, 3792, 2007. With permission.)

ground state destabilization.* The aforementioned MO analysis agrees well with this rationale but also points out to the importance of excited state stabilization in strained cyclic enediynes. The ground state destabilization and the excited state stabilization together should facilitate the photochemical Bergman cyclization in a synergistic manner. This expectation is fully confirmed by the available experimental findings (Schemes 23.7 through 23.10) of efficient photo-Bergman cyclizations in strained cyclic enediynes.

Popik and coauthors described photochemical ring contraction via the photo-Wolff rearrangement or CO extrusion from a cyclopropanone moiety that generates strained and thermally reactive enediynes (Scheme 23.20). Extrusion of CO proceeds efficiently and also can be promoted via low-energy two-photon absorption approach (the first report of two-photon-induced generation of reactive enediynes). In all of the reported examples, the following Bergman cyclization proceeds via thermal activation. It would be interesting to design systems in which the cycloaromatization step also proceeds photochemically via excitation of the initially formed ring contraction product.⁵⁹

23.3.2.2 Electronic Effects

Alternatively, the in-plane excitation energy can be lowered when the in-plane π -orbitals are incorporated in a more extended conjugated system. Several ways can be used to achieve this goal. For example, one

* Schreiner analyzed the Bergman cyclization of cyclic enediynes systematically using DFT analysis and found that the differences in reactivity are not solely based on strain effect. In particular, since alkyl substituents stabilize acetylenic bonds to a greater extent than olefinic bonds, alkyl substituents stabilize the starting material, thus increasing the activation barrier and the endothermicity. See Ref [20e].

can use conjugation from the acetylene end of the enediyne system by introduction of an appropriately oriented aryl and heteroaryl substituents at the terminal alkyne atoms. Extending the “in-plane” conjugation from the core is more difficult since one has to rely on either hyperconjugation or homoconjugation.

23.3.2.2.1 Conjugation at the Alkyne Termini

A potential problem with the enediyne activation through terminal aryl substitution is that the aryl group can be in conjugation with either the in-plane or out-of plane part of the acetylenic π -system depending on the relative orientation of the aromatic system. If the aromatic ring is in the plane of the enediyne moiety, then the aromatic π -orbitals are out-of-plane and do not conjugate with the in-plane orbitals responsible for the cyclization. Only when the aromatic ring is rotated out of the enediyne plane can the aromatic π -orbitals overlap with the in-plane π -orbitals of the enediyne system as illustrated in Figure 23.6.

This model rationalizes a number of experimental results discussed in the previous sections. In particular, it explains the contrasting reactivity of 1,6-diphenyl substituted enediynes discussed earlier. Table 23.1 illustrates that the results for the enediynes where the phenyl groups remain in the enediyne

FIGURE 23.6 Two conjugation modes for the in-plane π -system of enediyne moiety and effect of orientation of the aromatic ring on the conjugation with the enediyne system.

plane (rows 1–3 where the H–H distances are more than 2.5 Å) contrast the results for the row 4 where the terminal aryl groups are rotated out of the enediyne plane and conjugate with the in-plane orbitals of the enediyne moiety. The photo-Bergman cyclization was observed experimentally only in the last case.

Presumably, this effect can be amplified through introduction of larger substituents at the *ortho* positions of the terminal aryl/hetaryl groups. Steric repulsion between such substituents may force the aromatic rings out of the enediyne plane and enable their conjugation with the reacting in-plane system. The effect should be even more pronounced with polycyclic aromatics attached to the acetylenic ends. However, one has to be careful in avoiding those polycyclic moieties that may have their own photochemical reactivity and those *ortho* substituents that are so large that they destabilize the product due to steric crowding.⁶⁰

Potentially, *meta*-substitution may have a similar effect on the orientation of the terminal aryl groups. Note that introduction of a *meta*-substituent increased the cyclization yield from 13% to 44% in Scheme 23.5.²⁷ It is not clear, at this time, whether this increase results from the rotation of the terminal aryl group or from a manifestation of the photochemical “*meta*-effect.”⁶¹

23.3.2.2.2 Homoconjugation

The only way to influence electronic properties of the *in-plane* π -system from the “ene” end is to involve homoconjugation.⁶² Although homoconjugation is expected to be weaker than direct interactions, it provides an additional way to control the symmetry of the highest in-plane orbital, which can be useful for increasing the efficiency of two-photon excitation. The two-photon activation (TPA) of antitumor drugs is an especially useful for biological applications because it provides extremely mild conditions for the drug activation with photons of very low (near IR) energy and allows for photon delivery through the therapeutic window of tissues.⁶³ Additionally, the quadratic dependence of the two-photon absorption on the light intensity minimizes photo damage to the healthy tissue because it confines the affected part to the focus point of the laser, assuring excellent three-dimensional spatial control over the localization of the therapy.

Figure 23.7 provides an example of how homoconjugation can be used to control photophysical properties of the enediyne moiety. Introduction of two nitrogen atoms in the 1,4-positions of the aromatic ring adds another high-energy MO to the manifold of occupied in-plane orbitals. This orbital can be qualitatively described as a combination of the nitrogen lone pairs, which is symmetric relative to the plane of symmetry that bisects the enediyne moiety. Since this orbital is positioned between the frontier in-plane MOs of 1,2-diethynylbenzene, its presence decreases the gap between in-plane occupied and unoccupied orbitals. Different symmetry of this MO and potential electron transfer from the core to the alkyne termini associated with the excitation may be interesting in fine-tuning TPA of enediyne chromophores (*vide infra*).⁶⁴

FIGURE 23.7 The key in-plane molecular orbitals of *o*-diethynylpyrazine.

23.3.2.2.3 Combining In-Plane and Out-of-Plane Effects in “Forbidden”

Radical-Anionic Bergman and C1–C5 Cyclizations

Because the breaking π -bonds and the developing radical centers are orthogonal to the out-of-plane π -system and because the aromatic system develops mostly after the system proceeds through the transition state, the activation barrier for thermal cycloaromatization reactions is relatively insensitive to effects in the out-of-plane π -system. This provides a challenge for substituent control of such reactions, which often has to rely on indirect thermodynamic contributions to the reaction barrier as described by the Marcus theory.⁶⁵

As we discussed in the previous sections, communication of different electronic states plays an important role in the photochemical Bergman cyclization. Interestingly, the “forbidden” character of these cyclizations provides a way for the π and σ electrons to “communicate” with each other. As the result, even remote substituents can influence the cyclization. This phenomenon was investigated recently for photoinduced cyclizations of enediynes that proceed through a reductive single electron transfer to enediyne from a suitable donor.^{7a}

In both the Bergman cyclization and the C₁–C₅ cyclization, a σ -bond is formed at the expense of the same two in-plane π -bonds in either an endo-endo (Bergman) or an endo-exo (C₁–C₅) fashion. Both cyclizations of the parent enediyne should be forbidden in the excited state corresponding to the HOMO–LUMO excitation and both reactions have to go through a state crossing in the vicinity of the cyclization transition states. This crossing is a direct result of the bond-forming interaction that transforms the in-plane π -orbitals into a σ -bond and a pair of nonbonding MOs (two radical centers). In the reactant, both HOMO and LUMO correspond to out-of-plane orbitals yet both of the frontier MOs are localized at in-plane orbitals in the product.

In the radical-anionic version, the activation barrier for both C₁–C₆ and C₁–C₅ cyclizations of enediyne radical-anions can also be described as the avoided crossing between the out-of-plane and in-plane MOs (or electronic states that correspond to population of these MOs). One-electron reduction populates the out-of-plane LUMO (now the SOMO) of the enediyne moiety. At the TS (the crossing), the electron is “transferred” between the orthogonal π -systems to the new (in-plane) SOMO. Such a switch in MO populations should proceed through a crossing between electronic configurations with either an out-of-plane or an in-plane singly occupied MO (SOMO) along the reaction path (Figure 23.8).

This model successfully explains the acceleration of cyclization of radical-anions of benzannelated enediynes, the enhanced sensitivity of these cyclizations to π -conjugative effects of remote substituents and the fact that this selectivity is inverse compared to that of the Bergman cyclization.

The effect on the cycloaromatization potential energy surfaces of the parent enediyne is illustrated in Figure 23.9. Both directions of the ring closure become more favorable upon one-electron reduction. The cyclization barrier drops more significantly for the C1–C5 cyclization but the Bergman cyclization is still predicted to be kinetically favored. Interestingly, the latter is also predicted to be strongly exothermic (as opposed to the endothermic cyclization of the neutral enediyne).

Even more remarkable is how dramatic is the effect of one-electron reduction in benzannelated enediynes (Figure 23.10). Now the C1–C5 closure carries no thermodynamical penalty and becomes an essentially thermoneutral process with a relatively low barrier.

The large effect of benzannelation was shown to be due to the loss of aromaticity in the preexisting benzene ring of the benzannelated starting material upon its one-electron reduction. MO crossing moves the extra electron into the sigma framework where it does not interfere with the aromaticity. As the result, aromaticity of the preexisting ring A is restored in the TS (Figure 23.11). This rearomatization process is intimately connected with aromatization in the newly formed cycle B, overall providing a much stronger driving force for the radical-anionic cyclizations in benzannelated substrates.

Another interesting feature of these reactions is that they are predicted to be much more sensitive to the effects of remote substituents than the thermal Bergman cyclization of their neutral counterparts. In agreement with the experimental results of Russell and coworkers,^{22c,67} the influence of *para*-substituents

FIGURE 23.8 Crossings of in-plane and out-of-plane frontier MOs in radical-anionic Bergman and C1–C5 cyclizations (crossings for photochemical, dianionic, and radical-cationic cyclizations involve the same MOs but differ in the number of electrons). (From Alabugin, I.V. et al., *J. Am. Chem. Soc.*, 125, 14014, 2003 and reference therein. With permission.)

FIGURE 23.9 The reaction energy profiles for thermal (on the left) and radical-anionic (on the right) C1–C6 and C1–C5 cyclizations of parent enediyne **1** computed at the B3LYP/6–31G** level. on the thermal Bergman cyclization is small. The activation energies for the neutral substituents lie within a range of only 0.6 kcal/mol. On the other hand, effect of the same substituents on the activation energies of radical-anionic cyclizations is dramatic as illustrated by ~20 kcal/mol variation in the activation barriers in Figure 23.12.

The generality of these findings is enforced by the fact that reductive electron transfer can be accomplished in a variety of ways. For example, Whitlock et al.⁶⁸ showed that the cyclization of enediynes

FIGURE 23.10 The reaction energy profiles for thermal (on the left) and radical-anionic (on the right) C1–C6 and C1–C5 cyclizations of benzenelated enediyne **6** computed at the B3LYP/6–31G** level. (From Alabugin, I.V. et al., *J. Am. Chem. Soc.*, 125, 4495, 2003. With permission.)

FIGURE 23.11 The interplay of rearomatization and cycloaromatization in the radical-anionic C1–C5 cyclizations of 1,2-diethynylbenzene. Nucleus-independent chemical shift (NICS) values are computed at the B3LYP/6–31G** level. Positive NICS⁶⁶ values for enediyne radical-anion, which indicate antiaromaticity of the reactant, are changed to negative NICS values in the TS and the products of both C1–C5 and C1–C6 cyclizations. (From Alabugin, I.V. et al., *J. Am. Chem. Soc.*, 125, 14014, 2003 and reference therein. With permission.)

(Scheme 23.21) by lithium naphthalenide is dianionic and provides substituted fulvenes. The cyclization may proceed at either the radical-anionic or the dianion stage.

The dianionic cyclizations can also produce heterocycles. Tamao and coworkers reported that reduction of bis(phenylethynyl)dialkylsilanes with lithium naphthalenide leads to the formation of a cyclized product via endo-endo ring closure.⁶⁹ An analogous dianionic endo-endo cyclization of cyclic 1,2-bis(silylethynyl)benzene opens access to 1,4-dilithio-2,3-disilylnaphthalenes (Scheme 23.22).⁷⁰

Along the similar lines, Wenthold applied the radical-anionic activation to the Cope rearrangement,⁷¹ which can be considered a more saturated analog of the Bergman cyclization.⁵ He found the reaction to have an inverted potential energy surface where the open-shell intermediate is more stable than the corresponding diene. Consequently, one-electron reduction of 2,5-dicyano-1,5-hexadiene resulted in spontaneous cyclization under the experimental conditions. This finding directly supports the concept described in Figure 23.2 and Figure 23.8.

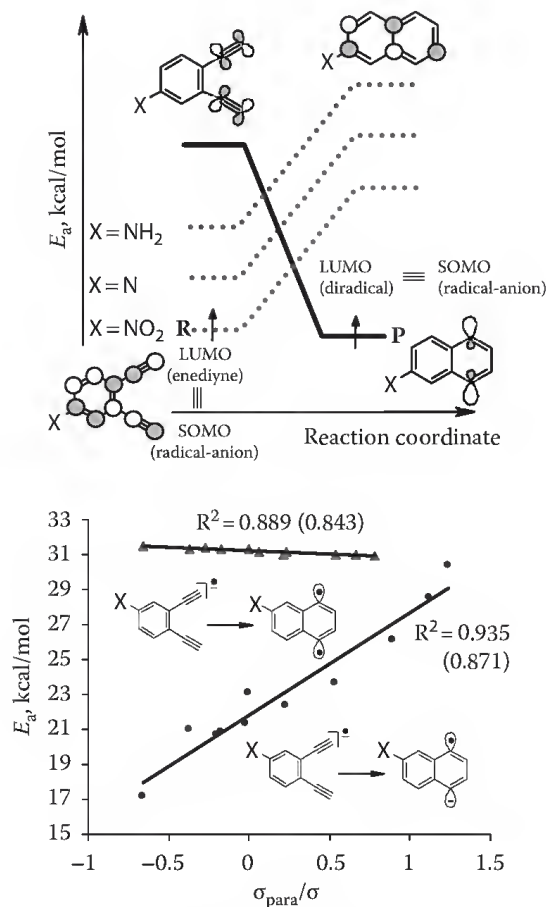

FIGURE 23.12 Top: The crossings of in-plane and out-of-plane frontier MOs in the radical-anionic Bergman cyclizations. Bottom: Correlation of UB3LYP(UBLYP)/6-31G** barriers for the radical anionic Bergman of substituted benzannelated enediynes with Hammett constants of remote substituents (σ^-) constants were used when available ($\text{X}=\text{NO}_2$, CHO , CN , F , Cl , OMe). Substituent effects on the C1-C5 cyclizations (not shown) follow an analogous trend. (Reprinted from Alabugin, I.V. et al., *J. Am. Chem. Soc.*, 125, 4495, 2003. With permission.)

23.4 Other Electronic Perturbations in the Enediyne Moiety

At this point, it is not clear how electronic effects known to be important for the thermal Bergman cyclization^{9b,10,11,22a-f,72,73} change their behavior in the photochemical version of this process. Based on the MO crossing model, the effects of *para*-substituents in the central ring of benzannelated enediynes may be even greater than such effects in thermal cyclization. Moreover, the substantial yield increase upon introduction of a *meta*-substituent in a terminal aryl group (Scheme 23.5) suggests the possibility of new electronic effects that are selectively applicable for the photochemical process, such as the photochemical *meta*-effect (also known as the *ortho,meta*-effect).⁶¹ If the *meta*-effect is substantial, the effect of *ortho*-substituents is likely to be significant too and should reveal itself not only through sterics^{64,74} but through an electronic interaction.

23.5 Control of Photo-Bergman Cyclization through Additional Excited States

23.5.1 Excited States Involving Coordinated Metal Ions

The work of Zaleski et al. combined the strain effects discussed earlier with unique electronic and structural features introduced by enediyne-metal coordination. New photochemical transitions derived from spatial overlap between the metal $d\sigma$ or $d\pi$ molecular orbitals and enediyne orbitals can lead to the development of new strategies for the initiation of Bergman cyclization with lower energy photons. In particular, vanadium (V) metalloenediyne compounds (Scheme 23.23) exhibited strong ligand-to-metal charge transfer (LMCT) transitions in the near-IR region because of low redox potentials of the high valent vanadium center and the easily oxidizable metal-binding motif.^{32a,75} These LMCT transitions were used to photothermally activate the metalloenediyne toward Bergman cyclization upon 785 nm laser excitation, despite the compound's relative inertness to photo-Bergman reactivity upon electronic

SCHEME 23.23 Photothermal cyclization of vanadium (V) metalloenediyne in the solid state. (From Kraft, B.J. et al., *Inorg. Chem.*, 42, 1663, 2003. With permission.)

SCHEME 23.24 (a) Photo-Bergman cyclization of copper metalloenediynes via metal-ligand charge transfer complex. (b) Relative energies of copper and ligand MOs proposed to be involved in the photoelectronic Bergman cyclization of Cu(I) and Cu(II)-metalloenediynes. (Reprinted from Kraft, B.J. et al., *Inorg. Chem.*, 42, 1663, 2003. With permission.)

excitation in the ultraviolet spectral region. Formation of black, sparingly soluble products with vibrational characteristics of poly(*p*-phenylene) together with the detection of high-molecular-weight species (MW up to 274,000 Da) suggests photopolymerization as the major process.

Photo-Bergman cyclization can also be promoted by charge transfer from metals to ligands (MLCT). Zaleski et al.⁷⁶ suggested that MLCT from the metal $d\pi$ orbital to the empty π^* orbital of the pyridine ring is responsible for the Bergman cyclization of the enediyne Cu(I) complexes in Scheme 23.24. Neither the uncomplexed ligand nor the analogous Zn complex was photochemically reactive. In the case of Cu(II) complex, the charge transfer from π -orbital of the pyridine to d -orbital of the metal results in a partial π -hole in the pyridine ring, which is transferred, to some extent, onto the enediyne unit. Thus, the photoreaction may involve an enediyne-centered state, despite initial population of the formal Cu-pyridine CT manifold.

SCHEME 23.25 Reduction of the porphyrin backbone during photolysis of tetraphenyl octakis (phenylethynyl) porphyrine. (From Chandra, T. et al., *Inorg. Chem.*, 42, 5158, 2003. With permission.)

A more detailed analysis with time-dependent density functional theory (TD-DFT) indicated that chelation to Cu(I) or Cu(II) creates several low-energy (<3.0 eV) charge transfer excited states. The multiconfigurational nature of the charge transfer excited states indicates the electronic similarities between the excited MLCT or LMCT configuration and the cyclization transition state electronic structure, which drives the Bergman cyclization of metallocenediynes. In agreement with the experimental data, the Zn(II) complex does not exhibit low-energy charge transfer states because of the poor energetic overlap between the Zn(II) d-orbitals and the pyridine orbitals, resulting in *cis-trans* photoisomerization.

Zaleski and coworkers also prepared an interesting family of enediynes based on the porphyrine core.⁷⁷ These porphyrinic enediynes (Scheme 23.25) show systematic red shifts in their electronic spectra as a function of the number of conjugated alkyne units (~13 nm/alkyne), which indicates participation of the enediyne units in the electronic excited states. Photochemical activation of the free base of tetraphenyl octakis(phenylethynyl) porphyrine derivative only led to the reduction of the porphyrin backbone via H-atom addition at the opposing *meso*-positions, suggesting significant activation barriers for the photo-Bergman cyclization.

A very interesting set of observations that correlated thermal and photochemical reactivity of porphyrine-based enediynes was reported recently by Zaleski and coworkers.⁷⁸ Unlike the previous example, electronic excitation of the porphyrine chromophore is capable of activating the acyclic enediyne unit toward cycloaromatization (albeit the reduction products have been formed as well). The cyclization efficiency depends, however, on the excitation wavelengths (35% vs. 15% vs. 6% of the photoproduct for the $\lambda \geq 395$ nm (Soret), ≥ 515 nm and ≥ 590 nm (Q-band) excitation, respectively). The initially formed cyclic product is trapped via radical addition to the adjacent *meso*-phenyl rings and subsequent rearomatization with the formation of final picenoporphyrin products (Scheme 23.26).

Barriers for the Bergman cyclization step in the excited state depend on the steric bulk of the substituents R at the alkyne termini. For R=H, the corresponding photoproduct is formed in up to 35% yield

SCHEME 23.26 Formation of picenoporphyrins from dialkynylporphyrinic enediynes. (From Nath, M. et al., *J. Am. Chem. Soc.*, 127, 478, 2005. With permission.)

SCHEME 23.27 Suggested reaction energy profiles for ground- and excited-state Bergman cyclization of porphyrin-based enediynes. (Reprinted from Nath, M. et al., *J. Am. Chem. Soc.*, 127, 478, 2005. With permission.)

even at $\sim 10^\circ\text{C}$ whereas irradiation of the diphenyl substituted enediyne produced only small amounts (5%–8%) of picenoporphyrin even at 125°C . Because no thermal Bergman cyclization has been observed at 125°C with $R = \text{Ph}$, this result suggests that the excited state cyclization barrier is still lower than the ground state barrier. Based on the comparison of thermal and photochemical reactivity for the two enediynes, the authors suggested qualitative potential energy surfaces summarized in Scheme 23.27. The presence of substantial activation barriers in the excited state hypersurface is consistent with the theoretical analysis of formally forbidden photo-Bergman cyclizations presented in Section 23.3.1.2.

An interesting variation where the photo-Bergman cyclization is inhibited by metal complexation as described by O'Connor et al.⁷⁹ (Scheme 23.28). In contrast to the parent benzannelated cyclic enediyne, its ruthenium complex did not produce any cyclized product upon photoactivation. The reluctance of this compound to be involved in photochemical cycloaromatization is tentatively attributed to decreased aromaticity in the incipient 1,4-diradical, potentially providing an interesting corollary to the results summarized in Scheme 23.8.

23.5.2 Intramolecular Electron Transfer

Schmittl and coauthors described a novel concept for activation of enediynes for DNA cleavage based on intramolecular electron transfer between a donor and an acceptor attached at the opposite enediyne termini.^{32b} There is evidence that the mode of action may involve a biscumulenenic

SCHEME 23.28 Inhibition of photo-Bergman cyclization upon Ru complexation.

SCHEME 23.29 Activation of enediynes through photoinduced intramolecular electron transfer. (From Schmitt, M. et al., *Chem. Comm.*, 7, 646, 2003. With permission.)

intermediate (Scheme 23.29). Although the exact fate of this intermediate is still speculative, the available experimental data suggest that this intermediate is capable of inducing efficient DNA cleavage (vide infra).

23.6 H-Abstraction Ability of Diradicals Produced in Thermal and Photochemical Bergman Cyclizations

A common theme in photochemical Bergman cyclizations discussed in the previous sections is the relatively low efficiency of *p*-benzyne trapping through H-abstraction. Very often, a large excess of the H-donor is needed to achieve high yields of cycloaromatized products.

In general, *p*-benzyne diradicals are known to be less reactive in H-abstraction reactions than the phenyl radical due to coupling between the two radical centers. The nonbonding electrons in diradicals can interact by either direct coupling through space (TS) or by indirect coupling through antibonding (σ^*) bridge orbitals (through bond (TB) coupling). In the ground state *p*-benzyne species, TB coupling

FIGURE 23.13 Singly occupied MO (SOMO) for *p*-benzyne radical anion. (From Alabugin, I.V. et al., *J. Am. Chem. Soc.*, 125, 14014, 2003 and reference therein. With permission.)

of the two σ radicals through σ^* bridge orbitals is the main conduit for the electronic interaction.⁵⁵ This interaction, which is absent in monoradicals and triplet *p*-benzynes,⁸⁰ provides an additional 3–5 kcal/mol of stabilization energy to *p*-benzyne-type diradicals. Since this stabilizing energy is lost with the first H-atom abstraction, the ground state *p*-benzyne diradicals are less reactive and more selective than simple phenyl radicals.

Interestingly, the magnitude of coupling between the nonbonding electrons increases dramatically in the radical-anionic cycloaromatization reactions.^{9b} In brief, this increase can be attributed to the fact that the LUMO of the diradicals, which is populated by the one-electron reduction, corresponds to a symmetric combination of the two nonbonding orbitals. This effect and the more spatially diffuse anionic orbitals allow for an increased direct through-space interaction of the two radical-anionic centers in *p*-benzyne (Figure 23.13).

The markedly increased coupling of non-bonding orbitals in σ,σ -radical-anions may be of general importance not only for radical-anionic reactions,⁸¹ but also for their photochemical analogues where the same MO is populated by excitation instead of reduction. Consequently, an adiabatic photochemical Bergman cyclization in the singlet state should lead to the *p*-benzyne intermediate having significant bonding character between the “radical” orbitals. This interaction can contribute to the relative inefficiency of H-abstraction by the photochemically produced *p*-benzynes, provided that such a diradical is converted into the ground state *p*-benzyne sufficiently slowly.

23.7 Photophysical Properties of Enediynes

Common photophysical considerations, such as excited state lifetimes, excitation energies, geometries of excited states, excited state potential energy surfaces, availability of relevant conical intersections, efficiency of intersystem crossing, molar absorptivities, and two-photon absorption cross section, are important for the development of photochemical reactions of enediynes. Detailed photophysical studies of these molecules are still rare. An exception to this rule is provided by a recent systematic analysis of photophysical properties of a family benzannelated enediynes.⁶⁴ Although this study concentrated on the two-photon excitation of these compounds, it provided useful basic photophysical information, which is summarized in Table 23.2.

All enediynes in Figure 23.14 showed two major absorption peaks, corresponding to the S1 and S2 excited states, respectively. According to TD-DFT analysis, in most compounds, the first excited state

has B symmetry with energies in the 300–360 nm range. This absorption is redshifted related to that of *o*-diethynylbenzene and nonbenzenoid enediynes, which absorb below 280 nm.⁸² The S1 energies are sensitive to the presence of donor and acceptor substituents and the lowest energy absorption peak for all the compounds except the two pyrazines corresponds to the first excited state of B symmetry. For pyrazines only, the lowest observed OPA (one-photon-absorption) state has A symmetry and corresponds to the excitation to the third excited state calculated by TD-DFT method. Since all the molecules have axial rather than central symmetry, both transitions conserving and changing symmetry are dipole allowed in the linear optical response.

The two-photon excited fluorescence (TPEF) spectra of these enediynes are identical to their one-photon emission spectra, indicating that the same excited state is ultimately populated. However, the TPEF is allowed only via two-photon absorption by the S2 (or higher) state of the enediynes. In perfect agreement with the experiment, the B states disappear from the picture in the two-photon computed excited states.

TABLE 23.3 Two-Photon Excited Fluorescence (TPEF) of Eneidyne

Compound	Excitation λ (nm)	$\lambda_{ex}/2$ (nm)	Relative Quantum Yield	Ratio of TPA Cross Sections, $\frac{\delta_n^{TPA}}{\delta_3^{TPA}}$
7	542	271	0.58	0.55
8	553	277	0.70	0.37

14	504	252	0.082	1.34
15	514	257	—	—

All TPA states have the same A symmetry as the ground state, mimicking selection rules for centrosymmetric molecules. However, unlike the centrosymmetric case, the state with the largest TPA cross section is also active (and even dominant) in the OPA spectrum. This observation can be rationalized by recalling that typically strong TPA activities are observed in the substituted chromophores in the direction of intramolecular charge transfer, which would correspond to the symmetry axis in this case. The summary for TPEF of eneidyne is shown in Table 23.3. TPA cross sections in benzannulated eneidyne are sensitive to substitutions at both the core and the periphery of the eneidyne chromophore: introduction of donor substituents at the core and strongly acceptor substituents at the periphery increase the TPA cross section.

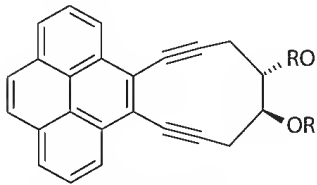

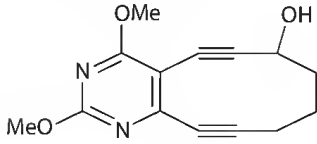

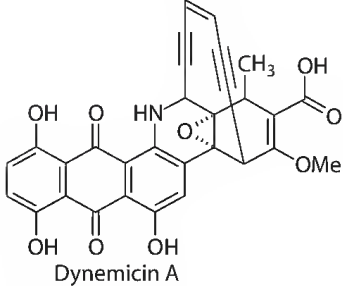

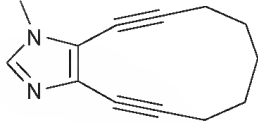

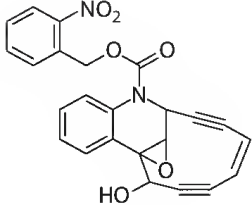

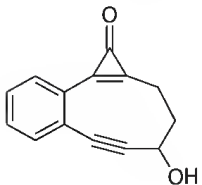

23.8 DNA Cleavage by Photochemically Activated Eneidyne

Reactive species generated from eneidyne upon photochemical excitation can potentially target multiple cellular targets. Because protein damage by eneidyne has been discussed in detail earlier,¹⁵ this section will concentrate on reactivity of photoactivated eneidyne toward DNA.

Comparison of reactivity of different eneidyne toward DNA is complicated by significant variations in experimental conditions such as eneidyne concentration, irradiation time, light intensity, irradiation wavelengths, as well as potential differences in the nature of chemical steps involved in the mechanism of DNA damage. Eneidyne-based DNA photocleavers may operate not only through a photochemical Bergman reaction but also via photoactivation of thermal Bergman cyclization via photolytic activation of eneidyne prodrugs, photothermal Bergman cyclization where excitation followed by radiationless decay provides thermal energy for the cyclization, C1–C5 cyclization, photoinduced electron transfer, direct H-transfer to an excited state of the reactant, as well as nucleobase alkylation. To further complicate the comparison, the efficiency of DNA cleavage depends not only on the efficiency of the radical-generating step but also from such factors as solubility in water, binding mode (e.g., intercalation vs. groove binding) and overall affinity to DNA, involvement of electron transfer in quenching of excited states and in the propagation of damage by hole- or exciton-hopping, the intermediacy of diffusing oxygen species etc. As the result, some of the illustrative data shown in Table 23.4 may reflect a complex combination of factors.

Interestingly, hybrid antitumor antibiotic dynemicin A (20 μ M) induces considerable DNA cleavage when activated by visible (<580 nm) light.⁸³ This process is suggested to proceed through photoreduction of the antibiotic quinone core, followed by a thermal Bergman cyclization. Natural eneidyne esperamicin and neocarzinostatin were also reported to cause DNA cleavage upon photochemical activation.⁹⁰ About 13% of ds DNA cleavage by 1 μ M esperamicin A₁ has been observed after 15 min of 254-nm irradiation. The exact chemical mechanism of these photochemical processes is still unknown

although spin-trapping experiments support radical species formation. Esperamicin shows the same base selectivity for the photochemical DNA cleavage and the usual, thiol-activated thermal pathway. In contrast, light-activated neocazinostatin attacks G-bases that are rarely damaged by the thiol-activated neocarcinostatin, suggesting that the involved chemistry is different for the photochemical DNA cleavage by this natural enediyne.

De novo designed enediynes can induce photochemical DNA cleavage as well. Whereas the ss cleavage is rather common, efficient ds cleavage remains a difficult goal to accomplish. This is an important problem because the ds DNA cleavage is much more difficult to repair and more important therapeutically than ss DNA cleavage.⁸⁴

Representative examples are summarized in Table 23.4. A water-soluble dialkynylpyrene reported by Funk et al.²⁹ provided some ds DNA cleavage at 20 μM enediyne concentration after only 15 min of irradiation. Pyrimidine alcohol (Scheme 23.10) yields significant DNA ss cleavage at 40 μM and signs of ds cleavage at 4000 μM under irradiation with 313 nm light.³⁰ A recent report of Zaleski et al. showed that copper complexes of bis(pyridine) enediynes lead to a mixture of ds and ss cleavage with complete consumption of the supercoiled plasmid DNA after 8 h irradiation at concentrations of enediynes in the range of 50–500 μM.⁸⁰ At the lower concentrations, only ss cleavage is observed. Schmitt et al. reported^{32b} that the mixture of ds and ss DNA cleavage was observed at the rather high (1 mM) enediyne concentration after 4 h of 419 nm irradiation.

These results do not suggest the relative inefficiency of the photo-Bergman cyclization in comparison to the thermal Bergman cyclization because most literature examples of DNA cleavages promoted by thermal activation of enediynes are ss cleavages as well. This lack of efficiency is not surprising because the two radical centers of a *p*-benzyne diradical should target the opposite DNA strands with 100% efficiency for the ds cleavage to occur. In practice, one of the radical centers is often quenched by reaction with the environment or by abstraction of hydrogen atoms from an already damaged strand ("silent damage"). Even the most efficient of natural enediynes, calicheamicin γ1 only leads to 1:2–1:3 ds:ss cleavage ratios.⁸⁵ Although these numbers still compare favorably with bleomycin-mediated DNA cleavage (1:6–1:20),^{86–88} there is clearly room for improvement.

FIGURE 23.15 *Left:* Photochemical conversion of ss DNA cleavage into more therapeutically important ds DNA cleavage through lysine-phosphate monoester recognition of the initial damage site. *Right:* Design of pH-dependent DNA cleavers based on different stages of protonation of the lysine side chain.

Designing a more powerful DNA-damaging warhead capable of a larger number of hydrogen abstractions provides a promising approach toward increasing the ds cleavage efficiency. In accord with these expectations, TFP-enediynes provide significant amounts of ds DNA cleavage at relatively low concentrations ($<10\ \mu\text{M}$). This efficiency stems from the fact that this reaction (C1–C5 cyclization) leads to the formal abstraction of four H-atoms (compared to only two H-abstractions in the Bergman cyclization). Not only is the increase in the net number of DNA-damaging events likely to result in the efficient abstraction of H-atoms and protons from the ribose backbone but these compounds can also damage DNA through a synergistic combination of oxidative damage (initiated via photoinduced electron transfer from DNA) and nucleobase alkylation.

The intrinsically high efficiency of ds cleavage by bis-TFP-enediynes can be improved even further by combining the light-activated part with functional groups capable of binding selectively to the site of an initial ss cleavage and transforming the easily repairable ss DNA damage into much more therapeutically important ds DNA damage (Figure 23.15, left).⁸⁹ Equally interesting is that this class of DNA binders displays pH dependency, which makes it suitable for selective targeting of cancer cells (Figure 23.15, right).

The pH-switching behavior of lysine-enediynes results in a dramatic increase in reactivity at the lower pH of hypoxic tumor cells. Remarkably, the change in reactivity occurs at a relatively narrow and predefined pH point ($\sim\text{pH } 6$). Molecular hybrids that combine lysine and TFP-substituted DNA photocleavers provide the DNA cleavage ratios of up to the 1:2 ds:ss at pH 5.5 at concentrations and irradiation times where almost no ds cleavage is observed at the pH of healthy cells (Figure 23.16).

Moreover, recent findings of efficient DNA cleavage by monoalkynes incapable of the Bergman or C₁–C₅ cyclizations^{34,92} and involvement of PET in the DNA damage by phenyl-substituted enediynes expected to undergo the photo-Bergman cyclization⁹² suggest that chemical mechanisms assumed in previous studies should be revisited.

Binding to DNA is also important for the efficiency of DNA cleavage. For example, bis-TFP-enediynes/lysine conjugates damage DNA through a complex mechanism that involves PET. Because this damage can be decreased by addition of chemical agents that can trap (Figure 23.17a). Other alternative photochemical pathways different from the photo-Bergman cyclization are also plausible as illustrated in Figure 23.18.

Interestingly, DNA cleavage with a related monoalkyne (Figure 23.17b) is less sensitive to the effects of the aforementioned additives, especially at the lower pH, suggesting that tight binding and efficient DNA cleavage without the involvement of diffusing species. The differences between the two DNA cleavers may be a consequence of their DNA-binding modes because the enediyne is an intercalator while the monoacetylene is a major groove binder according to a spectroscopic evidence.

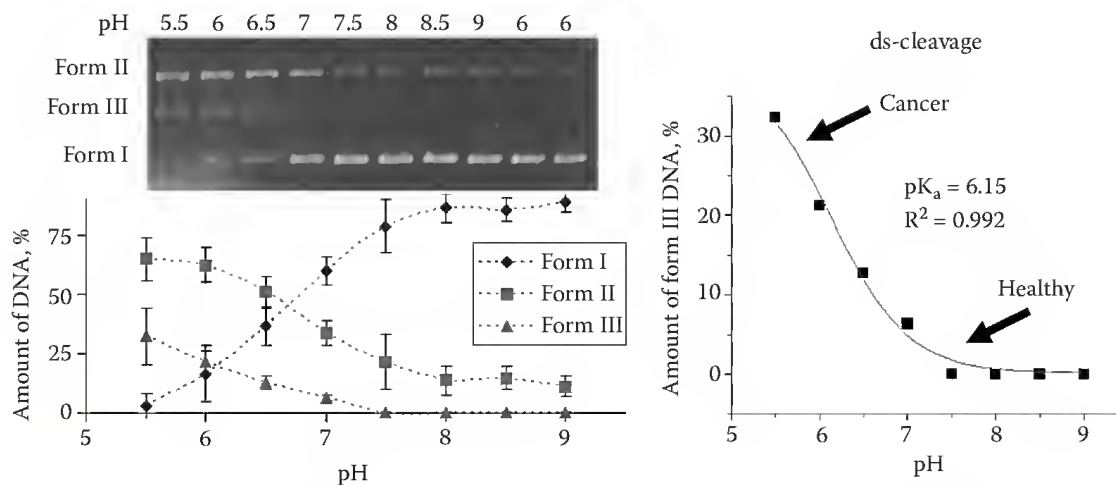

FIGURE 23.16 Left: Plasmid relaxation assays with TFP-acetylene-lysine conjugate (shown as entry 10 in Table 23.4, 15 μ M) and pBR 322 plasmid DNA (30 μ M/bp) in 20 mM phosphate buffer after 3 min of irradiation. Form I = intact supercoiled DNA, Form II = relaxed form (ss cleavage), Form III = linear form (ds cleavage). Lanes 1–8: from pH 5.5 to pH 9, lane 9: no compound + UV, lane 10: compound + no UV. Cleavage data were quantified through densitometry. Reported values represent the average of four experiments. Remarkably, the TFP-alkyne-lysine conjugates can destroy more than 90% of LNCap cancer cells in one treatment at concentrations as low as 10 nM. It is encouraging that, at these concentrations, toxicity without light is negligible. Similar increases in reactivity upon activation with light were observed in parallel experiments with UMRC3, UMRC6, and 786-O cancer cell lines.³⁴

23.9 Conclusion

The fast-growing body of research expanded our knowledge of photochemical reactions of enediynes and demonstrated the vast potential of these molecules as tools for efficient DNA modification and design of light-activated drugs.

Although it is clear now that efficient photochemical cycloaromatization reactions are possible, further research is needed to fully elucidate the electronic factors that control these processes. A robust theoretical model that incorporates the experimental data in a coherent and logical framework is needed for guiding the future development of this field.

The presence of the two orthogonal π -systems in alkynes is especially important for the understanding and control of photochemical cycloaromatization reactions where the two systems play complementary important roles. General understanding of the key photophysical processes and barriers on the excited state surfaces is still insufficient. Excited states that involve the in-plane MOs are likely to play the key role in the control of photochemical reactivity. Two-photon excitation of enediynes should be possible via inclusion of additional frontier MOs of different symmetry or excitation to a higher energy excited state.

From a practical perspective, it is important to increase the efficiency of ds DNA cleavage and develop a deeper understanding of the molecular details of DNA-enediyne binding and chemical mechanisms of DNA damage. From a synthetic perspective, it would be very interesting to harness the bond-forming potential of these processes in the design of efficient cascade sequences that open access to new conjugated materials.^{17c,45b,93}

24.1 Introduction

Ever since the introduction of the torsional potential curves for the excited states of ethylene [1], it became commonly accepted that the mechanism of photoisomerization of substituted ethylenes is torsional relaxation [2], that is, turning over one-half of the molecule around the formal double bond (also known as one-bond-flip [OBF]) [3]. This appears to be logical because the excited state bond order of the formal double bond is considerably reduced in both the excited singlet and triplet states [1]. However, in the 1970s, the observation of facile isomerization of polyene chromophores in confined media raised the question whether the volume demanding torsional relaxation mechanism can indeed take place within the observed picosecond or subpicosecond timescale [4]. Therefore, several less volume-demanding mechanisms for photoisomerization were proposed.

First proposed was the bicycle-pedal (BP) mechanism of photoisomerization [5] where two alternating double bonds in a conjugated system isomerize simultaneously (Figure 24.1). The only in-and-out-of-plane motion involved in this transformation is turning over of the two middle CH units while the remaining portions of the molecule remained in place. The stereochemical consequence is one-photon-two-bond isomerization. Very few examples of such two-bond isomerization have since been observed, limited to the energy downhill transformation of a di-*cis* moiety to a di-*trans* moiety (see more discussion in the following). This is in agreement with theoretical calculations showing that such processes in the excited singlet state are activated [6].

Subsequently the hula-twist (HT) mechanism of isomerization was proposed [3] in which two adjacent single and double bonds in a conjugated system rotate simultaneously (Figure 24.1). In effect, only one CH unit rotates in-and-out of the plane of the molecule while the remaining portions of the molecule

FIGURE 24.1 Three possible mechanisms of photoisomerization. *Top*: torsional relaxation where one-half of the molecule flips around the formal double bond (or one-bond-flip, OBF). *Middle*: the bicycle-pedal (BP) process that results in isomerization at two formal double bonds. *Bottom*: the hula-twist (HT) that results in configurational isomerization at one double bond and conformational isomerization at an adjacent single bond.

remain largely in-plane (or sliding in the plane of the molecule). Thus, it is also not volume demanding. And, the stereochemical consequence is simultaneous configurational isomerization of one double bond and conformational isomerization of the adjacent single bond. Calculations [6,7] have since shown that such processes are indeed energetically downhill from the Franck–Condon excited singlet species of the polyenes (described in detail later). Not surprisingly, many photochemical examples of simultaneous isomerization of double bond and single bond isomerization are now known (see the following). In this chapter, we wish to discuss the scope and limitation of photoisomerization by this mechanism.

24.2 Examples of Hula-Twist Photoisomerization

24.2.1 Early Examples

The first example of photoisomerization yielding a primary photoproduct that involved simultaneous double-bond and single-bond isomerization was that of pro-vitamin D, **1**, in EPA glass reported by Fuss and coworkers [8]:

Starting from the strained triene (obtained from ring opening of the corresponding cyclohexadiene isomer), the stable *trans* isomer **1** was obtained with an obvious simultaneous *s-cis* to *s-trans* conversion. Similarly, the more stable triene derivative was found to yield an unstable *trans* photoproduct.

This and other early examples of conformational changes of polyenes under UV irradiation were reviewed in our previous contribution [9]. This chapter will emphasize recent examples, the medium effects on the isomerization process, and clarification on perceived controversy on the HT mechanism.

It was known for some time that the medium exerts a strong effect on efficiency of photoisomerization. For example, Fischer [10] showed that the efficiencies of photoisomerization of stilbene were highly dependent on viscosity of the medium. In the case of the *trans* isomer, efficiencies of *trans* to *cis* isomerization dropped significantly upon an increase of solvent viscosity eventually becoming zero (only fluorescence was observed) when the solvent turned into a rigid organic glass. However, the drop of efficiency of isomerization of the *cis* isomer was less dramatic and reaction still persisted in organic glasses with efficiency less than one-third of that at room temperature [11]. Fisher [12] and, independently, Alfimov [13] were able to take advantage of this observation and produce unstable conformer of the *trans* isomer during low-temperature irradiation of a series of diarylethylenes.

24.2.2 More Recent Examples

The pioneering work of Fuss shed light on ways to design new systems and experimental conditions for detecting more examples of HT. The strategy was outlined in two papers [9b,c]. Many experimental examples have since appeared in the literature. These examples can be categorized in the following manner.

First, we should point out that to study HT isomerization, very often a strategically located substituent must be introduced. For example, for stilbenes, *o,o'*-disubstituted compounds, **2**, are quite suitable for producing the high-energy HT products; however, the corresponding *p,p'*-disubstituted compounds, **3**, are not (producing products indistinguishable from that of the OBF process [14]).

Simple styrene derivatives: Styryl compounds are the simplest systems that exhibit HT photoisomerization that can be readily detected by low-temperature UV spectroscopy. A simple example is compound **4** that was converted to a blueshifted product during low-temperature irradiation in EPA glass [14]. Upon slight warming, the product reverted back to the starting material. These transformations were also detected in argon matrix at liquid helium temperature, [15] where the recording of the infrared spectrum of the metastable photoproduct was possible.

Similar two-way interconversions were observed for more delocalized colored systems, **5–7** [16]. However, the shifts of absorption maxima were generally small, making the systems not particularly useful as new photochromic systems.

Stilbene derivatives: Low-temperature photoisomerization studies of a series of substituted stilbenes or 1,2-diarylethylenes were reported. The result of *cis*-*o,o'*-diphenylstilbene in *n*-propanol glass at 78 K (*cis*-**8**) [17] is typical of observations made for this group of compounds (Figure 24.2): an unstable isomerized photoproduct was formed, which rearranged to the stable conformer under mild heating.

Additionally, studies were carried out on conformationally restricted analog **9** [11], the corresponding seven- and five-ring compounds [18], and more delocalized systems **10** and **11** [18,19].

FIGURE 24.2 Low-temperature photoisomerization of *o,o'*-diphenylstilbene, *cis*-**8**, in *n*-propanol glass. *Left*: UV absorption spectra during progressive irradiation (>280 nm) to 9000 s. *Right*: difference absorption spectra ($t - t_0$) from spectra in left. *Insert*: final irradiated spectra (squares) and after warming to 200 K (circles) and re-cooled to 82 K (triangles up) showing transformation to the stable *trans*.

Diene derivatives: In addition to an earlier report of conformational interconversion during low-temperature irradiation of 1,3-butadiene [20], similar changes were also reported for substituted butadienes, **12**, in argon matrix [21]. More recently the study was extended to 1,1-diphenyl-1,3-butadiene, **13**, in organic glasses [22].

More revealing were the observations made with isomers of 1,4-diphenyl-1,3-butadiene and its derivatives [23]. Thus, irradiation of *cis*-**14a** in EPA glass was found to yield a thermally unstable conformer of the *trans,trans* isomer (Figure 24.3). The observation was inconsistent with OBF isomerization (giving the stable *trans,trans* isomer). Since a separate study with that of the parent *cis*-**14b** had ruled out HT-isomerization at carbon-2 (i.e., within limit of detection of ~5%), the observed result of *cis*-**14a** was only consistent with HT-1.

Low-temperature photoisomerization of *cis*-1,4-dimethyl-1,4-diphenylbutadiene was initially taken as an example of HT around a methyl group [24]. However, following the demonstration of the importance of local melting effect in low-temperature photochemical studies [17], it became clear that the result was also consistent with OBF photoisomerization in locally softened glasses (see more discussion on glass effect in the following).

FIGURE 24.3 Low-temperature (80 K) photoisomerization of *o,o'*-dimethyl-DPB, *cis*-**14a**, in EM (1:1 mixture of ethanol and methanol). *Left*: progressive changes of UV absorption spectra during 93 m of irradiation (>310 nm). *Right*: difference absorption spectra from left. *Insert*: Final irradiated spectra (broad structureless solid line) and after warming and recooling to 80 K (dotted line), identical to the structured band of the stable *trans,trans* isomer.

Trienes and longer polyenes: The only conclusive result on low-temperature photochemical studies of trienes was those of pro-vitamin D as described earlier [8]. *cis*-Isomers (1-*cis* or 3-*cis*) of 1,6-diphenyl-1,3,5-hexatriene were found to be stable under UV irradiation in organic glasses [25]. Photoisomerization of 2,5-dimethyl-1,3,5-hexatriene (**15a**) in argon matrix was reported [26]. However, because of the lack of conformational preference of the starting *cis* isomer, the observed result was not clear-cut as far as mechanism of reaction was concerned. Photoisomerization of the parent hexatriene (**15b**) was also studied under the condition of vapor deposition of the *cis* isomer. The results were not interpreted in terms of mechanism of photoisomerization [27].

Photochemical conformational reorganization (all-*trans* to 2-*s-cis*) of 1,3,5,7-octatetraene in *n*-octane crystals was reported in an early but elegant study [28].

Low-temperature photoisomerization of the hindered 11-*cis*-retinal (**16**) in EPA glass was reported [29]. The observed photochemical transformation followed by thermal rearrangements was consistent with HT-11 or HT-12 photoisomerization. (The results are different from those obtained in solution: giving the all-*trans* and 11,13-*dicis* isomers) [30]. Interestingly, as earlier reported, low-temperature irradiation of all-*trans*-retinal [31] was also consistent with multiple HT isomerizations yielding a highly blueshifted unstable conformer.

Nitrogen-containing compounds: Earlier we mentioned that the styryl derivatives yielded a slightly blue-shifted photoproduct when irradiated in low-temperature glassy media. However, for several nitrogen-containing compounds we found more extensive changes in UV absorption. One such example is the pyrrole derivative **17** [32]. The results are shown in Figure 24.4. The compound did not undergo detectable changes when irradiated into the longest absorption band (>360 nm). However, upon irradiation with shorter wavelength light (> 310 nm), there was a dramatic lowering of the absorption intensity of the longest wavelength band. This photochemical transformation was found to be reversible, that is, irradiating at even shorter wavelength (>250 nm) resulting in partial regain of the intensity of the longest wavelength band.

FIGURE 24.4 Wavelength-dependent, low-temperature photochemical reaction of push-and-pull dicyano compound **17**. *Left*: low-temperature (77 K) irradiation in EPA with light >360 nm (no change when irradiated with light >390 nm). *Right*: difference absorption spectra. *Insert*: absorption band before (squares) and after 2000 s of irradiation (circles), additional 30 s of irradiation with >300 nm light (triangles, up), followed by 1000 s irradiation of >360 nm light (triangles, down), demonstrating reversibility of the photoisomerization. Final line: after warming and recooling to 77 K (diamonds), identical to the initial line.

The N-atom in the 5-ring in **17** is nicely situated to interact with the remote electron-withdrawing groups in a charge-transfer manner. Hence, the compound is similar to those reported to exhibit TICT phenomenon [33]. We, therefore, believe that the long wavelength absorption was due to light excitation into the photochemically inactive charge-transfer band. Only when exciting into the higher energy π, π^* band, the normal HT isomerization was observed. However, the change of absorption bands was amplified by the difference in intensity of the charge-transfer bands with the highly twisted HT-product exhibiting a much weaker band of this type.

Similar behavior was detected in low-temperature photoisomerization of compound **18** [32]. However, the photoinactive long-wavelength band was completely in the visible region, making it and related compounds interesting candidates for photochromic studies. For the more delocalized diarylethylene derivative **19**, no wavelength-dependent photoisomerization was detected [32]. Apparently, the absence of strongly electron-withdrawing groups has ruled out the possibility of having a low-lying charge-transfer band. However, unstable photoproduct was produced for the *cis* isomer of **19**, similar to the diarylethylenes described earlier.

24.3 Complications in HT Photoisomerization Studies

HT is an ultrafast process directly originating from the Franck–Condon species of the excited singlet, kinetically competing against other fast decay processes. Therefore, production of the photoproducts is controlled by kinetic factors. On the other hand, in the triplet processes, such as in triplet-sensitized

reactions, photoproducts reflect the thermodynamic stability of equilibrated species in the excited state such as relaxed triplets (i.e., no HT is expected in triplet sensitized isomerizations). For a recent paper on triplet sensitized isomerization see Ref. [34]. Most of the reported successful studies on HT took advantage of the formation of thermodynamically unstable products, which however, could be detected only under conditions when trapping of such products was possible.

24.3.1 Detection Limitations

UV absorption spectroscopy is a convenient method for detecting formation of unstable (usually highly twisted hence blueshifted) conformer. The method will not be effective when there is no significant difference in relative stability of the reactant and the photoproduct (i.e., the latter present in an equilibrated mixture). Hence, for the following two isomers of naphthalene-substituted styryl derivatives, only the α -substituted isomer (**5**) will give a twisted, hence more readily detectable product while the β -isomer (**20**) will give a perturbed equilibrated mixture making its detection by UV a difficult proposition.

Also, the distinctly different absorption spectra of the unstable photoproduct(s) from that of the stable product were easily detected only in rigid organic glasses (often with vibrational structures). There were indications that in solution, even at low temperatures, such fine structures are no longer present (due to solvent broadening). This finding discouraged us from attempting ultrafast time-resolved UV absorption studies to detect the twisted HT product(s) [42].

Attempts were made to introduce the method difference FT-IR to detect formation of new photoproduct during irradiation of **1** in an organic glass, a technique successfully used in studies of primary photoproducts of the biopigments rhodopsin and bacteriorhodopsin [35]. Indeed, a unique IR spectrum was recorded. However, the assignment to the twisted conformer was ambiguous because the simulated IR spectra of the energy-minimized conformers do not match well with those observed for the proposed high-energy conformer nor for the starting stable conformer [36].

24.3.2 Glass Effects

While organic glasses have proven to be useful media for trapping metastable primary photoproducts, it was known for some time that such purportedly rigid media could easily soften under intense UV irradiation. Thus, Porter and coworkers [37] reported in their authoritative spectroscopic studies of trapped free radicals: "The excess energy in photolysis of ethyl iodide using radiation of 2537 Å, will amount to over 50 kcal/mole, and since a temperature rise of only 10°C is sufficient to produce noticeable softening of the glasses ..., each quantum absorbed by ethyl iodide should result in a viscosity-lowering of several hundred molecules of the solvent sufficient to enable the radicals to diffuse apart. Heat will rapidly be conducted away and the glass will again become rigid ..." Such local softening of the glassy medium is likely to have a more profound effect on stability of the high-energy conformer(s) produced by HT photoisomerization,

FIGURE 24.5 Glass effect on low-temperature photoisomerization of compound *cis*-8. *Left*: before and after irradiated spectra (at 82 K in *n*-propanol) from Figure 24.2 (*left*) superimposed with that after warming to 200 K and recooling to 82 K (triangles, up) and that of authentic sample of the stable *trans*. *Right*: similar irradiation carried out in EPA at 78 K and no significant changes after warming to 200 K and recooling to 78 K. Similar irradiation in *n*-propanol at 115 K also showed no significant changes detected after warming to 200 K and recooling to 78 K.

which disappears through unimolecular conformational reorganization (taking place rapidly at ~ 50 K) [28] rather than bimolecular radical–radical recombination in Porter’s case. We have demonstrated that indeed such glass-softening effect could take place if the glassy medium was not carefully chosen.

This is exemplified by the case of *cis*-*o,o'*-diphenylstilbene (**8a**) in EPA glass at liquid nitrogen temperature [17] (Figure 24.5). For the redshifted photoproduct, warming did not cause a change in the UV absorption spectrum, an observation normally associated with formation of stable product conformation (in disagreement with HT photoisomerization). However, EPA is a softer glass with setting temperature (~ 95 K) lower than that of *n*-propanol (~ 120 K) in which successful trapping of the high-energy conformer was already described (Figure 24.2).

Hence, in EPA, the excess heat from the absorbed photon can easily soften the glass molecules surrounding the substrate allowing the primary photoproduct to undergo thermal rearrangement to the stable conformer. Only in glasses of higher setting temperature (i.e., *n*-propanol), the dissipated excess thermal energy was not sufficient to soften the glasses, hence the photoproduct was successfully trapped. We further carried out irradiation of **8a** in *n*-propanol at a higher temperature (115 K). The result observed (Figure 24.5) was essentially the same as that in EPA at 82 K. Hence, at 115 K, even in *n*-propanol glass the unstable HT product could not be trapped.

This glass effect has since been demonstrated in other systems such as 1,1'-dimethylstilbene [32] and α,α' -dimethyl-1,4-diphenyl-1,3-butadiene (**14a**) [17]. It should be pointed out that soft hydrocarbon glasses such as *iso*-hexane or 3-methylpentane are particularly sensitive to the excess thermal energy effect. In the case of *iso*-pentane, it is doubtful that it can ever be used as rigid glass for any photoisomerization study at liquid nitrogen temperatures. In fact, Porter et al. specifically commented on the fact that in their hands *iso*-pentane remained fluid at such temperatures [37].

24.3.3 Regioselectivity

In the case of 1,4-diphenyl-1,3-butadiene, we reported exclusive detection of the HT-1 process at the expense of the HT-2 process [23]. In reality, when UV spectroscopy was used for detection of the primary photoproduct(s), it was unlikely that any minor product (say that from HT-2) could be detected if it were formed in less than one tenth of the primary photoproduct (that from HT-1). In the case of the parent 1,3-butadiene, we suspect HT-2 is a very minor process relative to HT-1. Its detection was

facilitated by the fact that the major HT-1 process did not give a new product when there was no stereochemical label at C-1. However, with a simple label at this position, OBF would lead to a product identical to that from HT-1.

Neither would there be detectable changes from HT-1 (at the α -carbon) of cinnamonnitrile that is different from OBF. However, in the case of ethyl cinnamate, **22**, HT-1 is detectable [38] giving a conformationally rearranged ester group in the product.

24.3.4 Alternative Mechanism, Examples of BP Photoisomerization

There are several cases in the literature where photoisomerization of crystalline polyenes resulted in two-bond isomerization in a manner consistent with bicycle-pedal (BP) process, that is, simultaneous isomerization of two double bonds. The first example was crystals of the *cis,cis*-muconate salt (**22**), rearranging directly to its *trans,trans* isomer [39]. Subsequently, other related examples later appeared in the literature: *cis,cis*-1,4-diphenyl-1,3-butadiene (**23**) crystals [40] and 1-*cis*,5-*cis*-1,6-diphenyl-1,3,5-hexatriene (**24**) crystals directly to the corresponding all-*trans* isomer [25].

It should be noted that the environment in a crystal cavity is very different from that in a glassy medium. For those di-*cis* isomers mentioned earlier, they all contain immobilized large head and tail making OBF or HT process not possible. On the other hand, the connecting middle diene moiety faces a relatively large intermolecular empty space that allows an energetically downhill (*cis,cis* to *trans,trans*) BP motion [39b]. The locally available empty space around the 11-*cis*-retinyl chromophore when coupled with the long tethers linked to the chromophore even allows a OBF process for photoisomerization of the visual chromophore [40b].

24.4 HT versus OBF

Liu and coworkers held the notion that OBF process is a preferred process for compounds isomerizing in unconfined environments such as in solution or in the vapor phase while HT is a preferred process in confined environment such as rigid organic glasses [9]. Fuss held a different and interesting view that

HT is the preferred process under all conditions of photoisomerization. Failure to detect HT product(s) under unconfined conditions was merely due to difficulties in accumulating the unstable conformer for detection [41]. It appears that a pulsed experiment with a specially designed system will be able to resolve this issue if a reliable spectroscopic method capable of distinguishing between conformational isomers can be devised. (A picosecond time-resolved study at room temperature was abandoned after demonstrating the close similarity of UV absorption characteristics of conformational isomers at elevated temperatures [43].)

However, if one considers that the deviation of the experimental data obtained in high solvent viscosity from the calculated Kramer equation for excited state lifetime of stilbene [43] is due to participation of HT process [44] that was not considered in the calculation, then one would reach the following conclusion. For solvents of low viscosity, the OBF process dominates, while for solvents of high viscosity the HT begins to play an increasing role, a conclusion that is a compromise between the views held by Liu and Fuss.

There are several papers in the literature questioning the necessity of invoking the HT process. Unfortunately, in these papers, either systems incapable of distinguishing between OBF and HT isomerization [40a,45] or the questionable *iso*-pentane glassy medium (see previous paragraphs) were used [45,46]. Thus, the results obtained were indeed those expected from OBF.

24.5 Theoretical Studies

Several theoretical papers confirming HT being an ultrafast or a low-energy pathway of decay for an excited polyene are available in the literature. Seltzer first showed by MNDO calculations [6] that both the OBF and HT photoisomerization of a model retinyl Schiff base did not require activation energy while isomerization by BP was activated. Higher order calculations showed that HT was indeed a low-energy decay pathway for excited hexatriene [47], octatetraene [48], and stilbene [49]. And, more recently decay pathways of butadiene [7b] and hexatriene [50] were shown to proceed via HT followed by pyramidalization of the HT carbon. The latter change nicely accounted for the well-known 1,5-H-migration process while not affecting the predicted stereochemical consequence of HT.

24.6 Conclusion

Hula-twist was first proposed as a volume-conserving photoisomerization reaction mechanism to account for the ultrafast rate of reaction of the retinyl chromophore confined in the binding cavity. Subsequent crystallographic evidence revealed that the retinal chromophore is not in close contact throughout the binding site. In fact, there are ample empty intramolecular empty spaces for the chromophore to execute the traditional OBF process. Nevertheless, the proposed simultaneous single-and-double-bond isomerization of HT has since been successfully detected in many examples of substrates trapped in the more closely interacting organic glassy media with products consistent with the expected stereochemical consequences (especially after removal of art effects such as softening of surrounding glasses). Whether HT is a general reaction mechanism for all isomerizations, including reactions under fluid solutions, remains to be established. There are also documented but limited number of examples of two double-bond BP isomerizations.

Fulgimides and their parent fulgides constitute a class of thermally irreversible photochromic compounds. Their derivatives are interesting building blocks for both material and life sciences, for example, for the switching of functions and the development of novel devices. The early work on fulgides in particular was directed toward memory devices, and they are still considered to be promising candidates for photon-controlled memory media. Fulgides and their derivatives as well as their applications have been the subject of various comprehensive reviews covering the literature up to 2004.^{1–4} In this chapter, we will discuss structure–property relationships observed over the years for furyl-, thienyl-, oxazolyl-, pyrrol-, 2-indolyl-, and 3-indolylfulgides and their fulgimide derivatives. The preferred notations furylfulgide, pyrrolfulgide, etc., will be used in this chapter. However, for a search of the published literature, the reader should also refer to the notations furyl fulgide, pyrrol fulgide, etc. Research toward applications in nanotechnology and biosensor technology is also covered, as well as synthetic methods for the preparation of fulgimides and recent advances in the preparation of their parent fulgides.

25.1 Fulgimides and Their Parent Fulgides: Structure–Property Relationships

Photochromic heterocyclic fulgides and fulgimides exist in three isomeric states: two open forms (*Z*- and *E*-form) and a closed *C*-form. Upon illumination with UV light besides other radiationless processes, three transformations occur: *Z*-to-*E* and *E*-to-*Z* isomerization and the *E*-to-*C* electrocyclization reaction.^{1–4} With *Z*/*E* isomerization, the light-yellow *Z*- and *E*-forms are reversibly converted into each other. Upon UV-light irradiation the *E*-form undergoes the conrotatory electrocyclic ring-closure reaction (coloring) furnishing the ring-closed, colored *C*-form. The reverse *C*-to-*E* ring-opening process (bleaching) is observed upon illumination with visible light. These two processes (coloring and

FIGURE 25.1 Photochemical isomerization of furylfulgides and furylfulgimides.

bleaching) are furnishing thermally stable isomeric states and are responsible for photochromism. Thus, the photochromic reaction is based on two reversible photon-induced concerted transformations of a hexatriene (*E*-form)—cyclohexadiene (*C*-form) system, in which both forms are thermodynamically stable (Figure 25.1).

Depending upon the heteroaromatic ring system it is often solely the *Z*-forms that are obtained via the common synthetic routes (e.g., furyl- and thienylfulgides).¹⁻⁴ However, the *Z*-forms have more or less been neglected within the photochromic systems. The *E*-to-*Z* and *Z*-to-*E* isomerizations complicate the photochromism of fulgides and fulgimides and are considered to be energy-wasting processes.

During the research period covered in this review, through to the beginning of 2010, there has been a focus on five main classes of heteroaromatic fulgides and fulgimides: thienyl- (2), pyrrolyl- (3), oxazolyl- (4), 3-indolyl- (5), and 2-indolyl derivatives (6). In slight contrast to this, Matsushima reported a comparative study of 14 heteroaromatic fulgides back in 1988.⁵ In these studies, 3-indolylfulgide (5), oxazolylfulgide (4), and the related thiazolyl fulgide showed very low thermal degradabilities, and 3-indolylfulgide (5) also showed low photochemical fatigues as compared to furyl-, thienyl-, and pyrrolyl derivatives. In these early days, a low photoresponsiveness for coloration was observed for 3-indolylfulgides since the quantum yield of 5 under UV irradiation was significantly lower compared to furylfulgide 1 (5: below 0.1; 1: 0.20).⁵ Nevertheless, during the last decade especially 2-indolylfulgimides, as well as Yokoyamas 3-indolylfulgimides, have been intensively studied (Figure 25.2).

Generally, the *E*- and *Z*-forms of these heteroaromatic fulgides display similar optical properties. Whereas the ring-opened *Z*- and *E*-forms are nonplanar (see e.g., 3-indolylfulgide 5), the ring-closed *C*-forms are almost planar, and as a consequence of their extended planar π -electron systems, a strong and broad absorption band in the visible wavelength range is observed. The absorption maxima

FIGURE 25.2 The five main classes of heteroaromatic fulgides (represented as *E*-isomers).

of the colored *C*-forms tend to redshift with the electron-donating ability of the heterocyclic groups: furyl < thienyl < *N*-methyl-pyrrolyl.⁵ In general, heteroaromatic fulgides and their derivatives show a good separation of the absorption spectra of the photochromic *E*- and *C*-forms.

Heller reported that the quantum yield for the *E*-to-*C* isomerization process (coloring) of furylfulgide **1** is independent of the reaction temperature and the irradiation wavelength, whereas for the *C*-to-*E* isomerization process (bleaching/decoloration) a strong dependence on both parameters was observed.^{6,7} A wavelength dependence of the *C*-to-*E* quantum yield for 3-indolylfulgides^{8,9} was also detected, and a series of theoretical papers report on the Arrhenius-type temperature dependence of the photochemical *C*-to-*E* isomerization.¹⁰

In the beginning, fulgides, which had a 2,5-dimethylfuryl moiety, were intensively examined on route to thermally irreversible photochromic compounds. Nowadays they are milestones in the research history of fulgides. In 1981 Heller reported the parent furylfulgide **1**,^{11,12} which contains the necessary methyl groups on the heterocyclic moiety to prevent the thermal ring-opening of the *C*-form by a disrotatory pathway. This was due to steric repulsion between the methyl groups in the ring-closed *C*-form.^{3,11–13} Some general trends within the substitution pattern of heteroaromatic fulgides and fulgimides can be described as follows:

In the furyl-, thienyl-, and 3-indolylfulgide series, bulky substituents R^1 (e.g., $R^1 = i\text{-Pr}$, $n\text{-Pr}$) at the methylene carbon next to the heteroaromatic ring increase the ring-closing *E*-to-*C* (coloring) quantum yield upon UV-light irradiation, while simultaneously decreasing the *E*-to-*Z* isomerization quantum yield (see structures **A** and **B**). With an isopropyl or *tert*-butyl group the *E*-to-*Z* isomerization can be completely suppressed.³ 2-Indolylfulgides **6**,^{14–17} in which R^1 is a hydrogen atom, are photochromic, in contrast to the related 3-indolylfulgides³ and the five-membered heteroaromatic fulgides with $R^1 = \text{H}$, which are not photochromic. For example, the *E*-form of 3-indolylfulgide **5** upon irradiation at 365 nm only undergoes *E*-to-*Z* isomerization.¹⁸ Another general trend already studied in the early days of research is observed upon replacement of an isopropylidene group (R^2) by an adamantylidene group (R^2).¹⁹ The bulky adamantylidene substituent is found to increase the ring-opening *C*-to-*E* (bleaching) quantum yield upon irradiation with visible light (Figure 25.3).

When fulgides were still a new topic, most research efforts focused on useful fulgides and fulgimides for rewriteable memory media. Accordingly the following properties amongst others were considered to be of major importance: (a) fatigue resistance, (b) nondestructive readout ability, and (c) thermal stability of the photochromic *C*- and *E*-forms. For example, early studies by Matsushima observed that an *N*-benzylfulgimide showed poor photochemical fatigue resistance in comparison to the parent furylfulgide **1** when undergoing repeated bleaching–coloration cycles in toluene upon irradiation with UV light. However, the thermal storage stability of the *C*-form of the fulgimide in toluene–ethanol solution at room temperature was significantly improved in comparison to the parent fulgide.^{20,21} Most important for fatigue resistivity is the elimination of oxygen from the photochromic system and to avoid benzyl and allyl substituents.

In comparison to furyl-, thienyl-, and pyrrolyl derivatives, other heterocyclic systems, especially 3-indolyl- and oxazolylfulgides, show excellent fatigue resistance during repeated bleaching–coloration

FIGURE 25.3 Substitution pattern of furyl-, thienyl-, and 3-indolylfulgides and furylfulgimides.

cycles, for example, in PMMA films containing 15–20 wt% of fulgide. 3-Indolyl derivatives also possess low medium dependence compared to the five-membered heterocyclic systems.^{5,22} The dilemma that was already observed in early days is the fact that highly resistant photochromic compounds generally offered only a low photoresponsiveness for coloration upon UV irradiation.⁵

In the following sections, the development of thermally stable and photochemically fatigue-resistant heteroaromatic fulgides and fulgimides is highlighted for the particular classes of heteroaromatic ring systems listed earlier. Selected data dealing with specific substitution patterns are discussed in these specialized sections.

Nowadays, fulgimides replace fulgides to reduce solvolytic degradations without affecting the photochromic performance.^{1–4} The imide functionality was used for attachment to the side chain of polymers but also to incorporate the photochromic unit into the main chain of polymers. Linkers were introduced via the imide group for coupling of the molecule to proteins. Fluorescence dyes and other chromophores were also attached via the imide functionality to the photochromic unit. Specific compounds and applications are discussed in the following sections.

25.1.1 Thienyl-, Pyrrolyl-, and Oxazolylfulgides and –Fulgimides

Upon introduction of an electron-donating substituent to the thienyl ring of thienylfulgides and their derivatives, a bathochromic shift of the absorption maximum was observed with an increase of the molar absorption coefficient (ϵ_{max}) being detected for the C-form. At the same time it was noted that the C-to-E (bleaching) quantum yield decreased.²³ Port observed that thienylfulgide **2** in PS can be colored and bleached at all temperatures between 300 and 10 K.²³ The molecular structures of a series of thienylfulgimides **7–14** with linkers attached to the imide functionality are shown in Figure 25.4. The photochromic properties of these compounds have been reported by Effenberger (**7**),²⁴ Rück-Braun (**8,9**),²⁵ Krayushkin (**10,11**),²⁶ Fox (**12,13**),²⁷ and Köse (**14**).²⁸

More recently there was a detailed study of pyrrolylfulgides by Fan.⁴ During studies using nanosecond laser flash photolysis they found that the E-to-C cyclization reactions of pyrrolylfulgides occur from the π - π^* excited singlet state. Furthermore, from their results they were able to conclude that the π - π^* excited triplet state was also involved.^{29–31} Matsushima (**15,16**),^{5,32,33} Chen (**17,18**),^{34,35} and Yao³⁶ reported the photochromic properties of some pyrrolylfulgimides (Figure 25.5).

Oxazolylfulgides and their derivatives are known to be fairly thermally and photochemically stable. This is explained by the higher oxidation potentials of the oxazole ring.³⁷ A selection of oxazolylfulgides and fulgimides (**19–22**)^{38,39} from the literature is shown in Figure 25.6.

More recently, the photochromic properties of cationic oxazolylfulgimides **23–27** were examined in neutral aqueous solution.^{21,33} In addition to this, the photochromic properties of the neutral precursors

FIGURE 25.4 Molecular structures of a series of thienylfulgimides.

FIGURE 25.5 Molecular structures of a series of pyrrolylfulgides and pyrrolylfulgimides.

FIGURE 25.6 Molecular structures of a series of oxazolyfulgides.

(23,25) were compared with their allylated cationic derivatives (24,26,27), which were measured in methanol. The introduction of the cationic electron-withdrawing substituent at the phenyl ring, attached to the oxazole ring, led to large shifts of the electronic transitions and to significant changes in the photochromic response rates. Similar effects and trends were observed upon allylation of a dimethylamino group in the *para*-position of a phenyl ring at the imide nitrogen. From the results obtained, Matsushima concluded that the majority of the photochromic phenomena known from organic media and solvents are also observed in aqueous or hydroxylic media.²¹ Not long ago the use of dibenzyl fulgenate derivative of the parent oxazolyfulgide in rewritable films was reported.³³ The colored C-form of this fulgenate led to a hypsochromic shift of the absorption maximum to 405 nm and to a larger absorption coefficient when compared to the C-form of the parent oxazolyfulgide. This fulgide derivative was applied in the development of simple full-color rewritable films, in combination with other fulgide derivatives (Figure 25.7).

FIGURE 25.7 Molecular structures of a series of oxazolyfulgimides.

25.1.2 3-Indolylfulgides and 3-Fulgimides

Analogous to furylfulgides, bulky alkyl substituents (R^1) at the methylene group besides the indole ring increased the coloring quantum yield, whereas a bulky alkylidene groups (R^2) increased the bleaching quantum yield, see structure **B**. However, if R^1 and R^2 are both sterically demanding the coloring quantum yield decreased and only an increase of the bleaching quantum yield was observed.¹⁹ For a related study of the consequences of miscellaneous alkyl substituents in position R^1 on a 3-indolylfulgimide were determined.⁴⁰ (Figure 25.8).

In early days already electronic and steric effects of substituents on the indole ring were investigated.^{3,41,42} Electron-donating substituents (MeS, MeO, Me₂N) in the 5-position of the indole ring red-shifted the absorption maxima of the colored C-forms, but also decreased the quantum yields of the photoreactions.^{22,41} The colored form of 5-dimethylamino-substituted indolylfulgide was found to be highly resistant toward photobleaching.²² However, a methoxy group in the 6-position of the indole ring resulted in a higher molar absorption coefficient.⁴³ For two methoxy groups on the indole ring in 5- and 6-position both effects were observed.⁴³ Replacement of the methyl by an ethyl group in 2-position (R''') also redshifted the absorption maxima of the colored C-form but also lowered the molar ratio of the colored form in the photostationary state upon UV irradiation (examples for molar ratios: **5** $R''' = \text{Me}$, E/Z/C 35/9/56;¹⁹ **32**: $R''' = \text{Et}$, E/Z/C 39/31/30¹⁹; and **30**: $R' = \text{NMe}_2$, E+Z/C 3/97²²) (Figure 25.9).

During the studies with 5-dimethylaminoindolylfulgide **30** a new type of nondestructive readout methodology, using an acid–base equilibrium was discovered. The C-form of **30a** showed absorption at 780 nm and it did not bleach upon irradiation with visible light.^{22,41} However, upon treatment with trichloroacetic acid, a mixture of the parent fulgide C-**30a** and its protonated species C-**30b** formed an equilibrating system.⁴⁴ The protonated species C-**30b** had no absorption at 780 nm and underwent ring-opening upon irradiation with 554 nm light to a protonated E-form E-**30b**. This equilibrium mixture is regarded to be an ideal nondestructive readout system, using 403 nm light for writing, 554 nm light for erasing, and 780 nm light for readout.^{3,45} The phenomena were also observed in different PMMA films (Figure 25.10).^{9,46}

FIGURE 25.8 Photochromism of 3-indolylfulgides and 3-indolylfulgimides.

FIGURE 25.9 Substitution pattern of a series of 3-indolylfulgides.

FIGURE 25.10 Molecular structures of the *E*- and *C*-isomers of 5-dimethylaminoindolylfulgide **30** and its protonated forms.

A selection of 3-indolylfulgides (**34**,**35**) with additional modifications on the indole ring is presented in Figure 25.11.^{33,47}

Electronic effects of substituents on indole nitrogen were also investigated (Me, Et¹⁹ and H, Ts⁴¹) by Yokoyama (see structures **C** and **D**). The photochromic properties of indolylfulgide **32** observed upon replacement of the methyl group by an ethyl group were reported to be almost the same as observed for **5**, however, an increase of the molar ratio of the *C*-form in the photostationary state upon UV-light irradiation was observed (see structure **D**: $R^3 = Me$, $E/Z/C = 35/9/56$, $R^3 = Et$, $E/Z/C = 22/10/67$).¹⁹ The electron-withdrawing group ($R^3 = Ts$) shortened the absorption maximum of the colored form, suppressed thermal *E*-*Z* isomerization, and enlarged the quantum yield of the photochromic reactions.⁴¹ More recently Russian researchers also reported on the use of *N*-aryl substituted indolylfulgides (Figure 25.12).⁴⁸

A CF₃ group placed on the methylene group next to the indole ring ($R^1 = CF_3$) increased the ring-opening (bleaching) quantum yield significantly.⁴⁹ The absorption maximum of the open form was shifted

FIGURE 25.11 3-Indolylfulgides **34**, **35**: Modifications of the substitution pattern of the indole ring.

FIGURE 25.12 Substitution pattern of a series of 3-indolylfulgides.

toward longer wavelengths, whereas the absorption maximum of the closed form was observed at slightly shorter wavelengths.⁴⁹ Similar trends were observed by Lees within a series of fluorinated indolylfulgide ($R^1 = \text{C}_2\text{F}_5$ or a C_3F_7) derivatives, either containing the adamantylidene or the isopropylidene moiety.^{50–57}

Lees intensively studied the thermal stability of fluorinated indolylfulgides and related fulgimides. A CF_3 group increased the thermal stability of the closed form, decreased the thermal stability of the open form, and increased the photochemical repeatability. Recently the fluorinated substituents at the methylene group next to the indole ring were replaced by a carboxylic acid residue. This modification led to water solubility and according to Lees resulted in the most robust 3-indolylfulgide and derivatives published in the literature.⁵⁶

The thermal stabilities of the colored C-forms of 3-indolylfulgides and their derivatives were investigated, for instance by thermal degradation studies of the colored C-forms in PMMA films in the dark at 323 or 353 K. Excellent stabilities for indolylfulgides were detected in comparison to the fairly good stability of thienylfulgides, and only poor stabilities of furyl- and pyrrolylfulgide compounds.⁵ The parent indolylfulgide **5** was also trapped as a model compound in various media at different pH values as well as in a sol-gel matrix.⁵⁸

A series of chiral derivatives was prepared and investigated from indolylfulgides with variable substituents R^1 , for example, (R)-binaphthol-condensed indolylfulgides.^{59–63} However, this topic has been extensively reviewed in the past, and therefore is not covered in this chapter.^{64,65}

However, most importantly, for derivative **36** ($R^1 = n\text{-Pr}$) compared to **37** ($R^1 = i\text{-Pr}$) a 10-fold increase in fluorescence intensity was detected. Upon excitation with 470 nm light or 320 nm light, the C-form of the *n*-propyl-substituted indolylfulgide **36** fluoresced at 610 nm (Figure 25.13).⁶⁶

Russian authors in 2008 reported on the fluorescence characteristics of a series of 1-aryl-5-methoxy-indolylfulgides **38–40** observed in toluene at 293 K. Excitation of indolylfulgide **40** at 380 nm and 640 nm led to emission at 800 nm.⁴⁸ This is remarkable, because earlier the colorless *Z/E*-forms and the colored C-forms of furyl-, thienyl-, and indolylfulgides⁶⁶ were only found to emit fluorescence at low temperature (Figure 25.14).

FIGURE 25.13 Chiral derivatives of 3-indolylfulgides: (R)-binaphthol-condensed indolylfulgides **36**, **37**.

FIGURE 25.14 Molecular structures of a series of 1-aryl-5-methoxy-indolylfulgides.

25.1.3 2-Indolylfulgides and 2-Fulgimides

There are many interesting spectroscopic and photochromic properties of 2-indolylfulgides and their derivatives.^{16,17,67–78} The most significant for the *C*-form of 2-indolylfulgides is that the absorption maximum is observed at a longer wavelength, in addition to emitting fluorescence at 678 nm when irradiated with visible light of 580 nm. Thus, illumination of the ring-closed *C*-form with visible light leads to the electrocyclic ring-opening to the *E*-form, fluorescence of the *C*-form, and radiationless processes. The quantum yield for the *E*-to-*C* ring-closure (coloring) process was compared to other heteroaromatic fulgides and was found to be the same as that of the analogously substituted furylfulgide and thienylfulgides but higher than the quantum yields of 3-indolylfulgides.⁷⁸ It was observed for 2-indolylfulgides and their derivatives that the quantum yield of the *C*-to-*E* ring-opening (bleaching) process is strongly dependent on the polarity of the solvents. In polar solvents the quantum yield decreased. The low quantum yields observed were explained by the existence of strong interactions between a charge-separated state of the excited molecules with polar solvents leading to an increase of the activation energy for the ring-opening pathway (Figure 25.15).

Analogously to the earlier studies on 3-indolylfulgides and derivatives, the influence of the substitution pattern at the indolylmethylene moiety of 2-indolylfulgides was investigated, as well as the effects of substituents at the 5-position on the indole ring (see structure F) and at the indole nitrogen atom.

FIGURE 25.15 Photochemical isomerization of 2-indolylfulgides and 2-indolylfulgimides.

FIGURE 25.16 Substitution pattern of 2-indolylfulgides.

In comparison to the nonsubstituted parent fulgide **6**, a methyl group in position R^1 increased the *E*-to-*C* (coloring) quantum yield, however, concurrently the fluorescence quantum yield decreased (see structure **E**). Similar to the effects observed in the 3-indolylfulgide series an isopropyl substituent in position R^1 almost completely prevented the *E*-to-*Z* isomerization. Nevertheless, a methyl or an isopropyl group also decreased the fatigue resistance of 2-indolylfulgides.⁷¹ Photochemical decomposition of 2-indolyl- as well as 3-indolyl-fulgides⁴⁹ and derivatives is considered to be complicated and medium dependent.⁷¹ However, Yokoyama and Rentzepis concluded from their independent experiments that hydrogen atom abstraction from the alkyl group in position R^1 by the neighboring carbonyl oxygen of the fulgide/fulgimide moiety in the excited state might be a serious side reaction, responsible for the low fatigue resistance observed during repeated coloration/bleaching cycles, especially in the presence of an electron-rich isopropyl residue (Figure 25.16).

Electron-donating substituents in 5-position of the indole ring (see structure **F**) resulted in a bathochromic shift of the absorption maxima of the *C*- and the *E*-form, yet the substituents investigated ($R' = \text{OMe, Me, H, Cl, F}$) were found not to affect the fatigue resistance. However, upon placement of a methoxy group in 5-position a dramatic decrease of the *C*-to-*E* (bleaching) quantum yield was observed. Obviously, the *C*-form is stabilized by resonance effects between an electron-donating substituent in 5-position and the imide moiety. A related resonance stabilization has previously been observed in the 3-indolyl series, however, between the 5-substituent and the indole nitrogen but only with a dimethylamino group.^{9,44}

For the synthesis of a series of *N*-substituted fluorescing 2-indolylfulgimides from the parent fulgides, Rentzepis reported a Lewis acid and hexamethyldisilazane-promoted one-pot reaction.¹⁷ The photo-physical characteristics of the fulgimides were found to be similar to the values of the parent fulgides. Again the quantum yield for the *E*-to-*C* ring-closure process was found to be solvent dependent, and when switching from a nonpolar solvent (hexane) to a polar solvent the quantum yield increased by a factor of 2.

25.2 Synthetic Methods for the Preparation of Fulgides and Fulgimides

To date, the syntheses of fulgides have generally been achieved via Stobbe condensation of ketones **G**.¹⁻⁴ However, a key step of an alternative route toward fulgides with a sterically demanding *tert*-butyl group in position R^1 is the palladium(II)-mediated carbonylation of 2-butyne-1,4-diols.⁷⁹⁻⁸¹ For the Stobbe condensation with the diethylisopropylidenesuccinate **H**, lithium enolates were most commonly used.¹⁻⁴ These were obtained by treatment of the former succinate ester with lithium diisopropylamide. However, sodium hydride was also successfully used as a base in a number of papers⁷¹ and potassium *tert*-butoxide in *tert*-butanol was also found to be a good alternative.^{18,82}

Nevertheless, the synthesis of heteroaromatic halfesters **I** from electron-rich aromatic ketone precursors did not always proceed smoothly and then cerium enolates were successfully applied instead.²² In certain cases, the formation of lactone intermediates was reported, which were hydrolyzed to the

half-esters, for example by treatment with sodium hydride in DMF,⁵² or with potassium *tert*-butoxide/*tert*-butanol.⁸² More recently, yields were also improved by the application of potassium hexamethyldisilazide followed by treatment with potassium *tert*-butoxide/*tert*-butanol.⁸³

By saponification of the half-esters **I** with potassium hydroxide in refluxing ethanol, the diacid **J** is obtained. For the subsequent dehydration to the fulgides **K** acetylchloride,^{16,71} and acetic anhydride⁵² were used in most published procedures. However, dicyclohexylcarbodiimide^{71,84} or a water-soluble carbodiimide⁸³ was also successfully applied as dehydration reagents, in addition to 1-trifluoroacetylimidazole⁴¹ or carbonyldiimidazole.²⁶

By aminolysis of the fulgides **K** (anhydride ring opening), an isomeric mixture of the corresponding *N*-substituted succinamic acids **L** is obtained.^{16,25,52,56,71,83} In this transformation, the reactivity of electron-poor anilines was enhanced by metallation with sodium hydride NaH or lithium diisopropylamide (LDA).⁵⁵

For the dehydration to the fulgimide **M**, either acetyl chloride or acetic anhydride under thermal conditions was previously used in analogy to the fulgide formations.^{55,56} More recently, microwave-assisted one-pot syntheses proved to be superior in comparison to thermal methods, because side reactions are being reduced.^{85,86} Rentzepis and others used zinc chloride and hexamethyldisilazane to promote a one-pot procedure of the ring-opening of a fulgide with amines to the succinamic acids **L** and subsequent ring-closure to the fulgimides **M**.^{17,83} The synthesis of fulgimides has also been achieved by base-catalyzed cyclization of the methyl esters⁸⁷ or the phenacyl ester²⁵ of the succinamic acids (Figure 25.17).

FIGURE 25.17 General synthetic routes to fulgides and fulgimides.

25.3 Photophysical Studies of the Photochromic Mechanisms

The photophysical studies dealing with fulgides and their derivatives have been very well covered in recent review articles.⁴ Following this, the ultrafast dynamics of photochromic fulgides and fulgimides were completely evaluated and characterized, for example, by Braun and Zinth,^{88–94} as well as by other research groups.⁹⁵ Therefore this work is not covered in this chapter.

25.4 Fulgides and Fulgimides for Optical Recording Media

From the beginning, fulgide research was directed toward application in memory devices. This topic was extensively covered in previously published reviews.^{1–4} Over the years it became obvious that most of the heteroaromatic fulgides underwent extensive photooxidative degradations upon preparation and handling of the spin-coated polymer films in air.^{5,32,37,39} It has been shown that the degradation could be substantially suppressed and the thermal stabilities slightly improved by sealing the films with an adhesive to keep them airtight.^{38,96} In early studies conducted by Matsushima, furyl-, thienyl-, thiazolyl-, and oxazolylfulgides along with a furylfulgimide were investigated.³⁸ In 2005, Matsushima reported on the use of pyrrolylfulgides as cyan dyes in polymer films³² and in 2009 he reported on the application of oxazolylfulgenates as yellow dyes in full-color rewritable films.³³ PMMA was doped with a pyrrolylfulgide and was used for holographic recording.³⁵ A pyrrolylfulgide in combination with an oxazolylfulgide was also used in dual-wavelength optical memory for parallel recording.^{34,36} Multilevel recording of a photochromic *N*-benzyl indolylfulgide was also investigated.⁹⁷ For studies where the molecule was incorporated in hydroxylic solid films water-soluble cationic oxazolylfulgimides have been prepared and examined.²¹ The cationic derivatives were prepared from the parent fulgimide by allylation using allyl bromide. The fulgimide derivatives were chosen because of their higher stability toward solvolytic degradation in hydroxylic media. A series of novel thienylfulgimides for the development of recording media was also reported more recently by Krayushkin.^{26,98}

Within a series of papers, Rentzepis put forward 2-indolylfulgimides and derivatives for optical storage devices.⁶⁸ Photochromic cross-linked copolymers were derived from methyl methacrylate monomer and the fulgimide monomer **42**,⁷⁰ and more recently copolymers containing azobenzene and fulgimide units, for example, **43**, were also investigated (Figure 25.18).^{99,100}

Rentzepis developed an energy transfer dyad **44** consisting of a 2-indolylfulgimide and covalently attached strongly fluorescing oxazine dyes.^{67,74,76} The dyes ideally performed in a PMMA disk resulting in an erasable, rewritable molecular optical storage medium with nondestructive read-out. For data storage, the polar *C*-form of the photochromic unit was ring-opened with 530 nm light. Read-out was achieved by measuring the fluorescence of the oxazine dye upon irradiation at the 650 nm absorption maximum. This fluorescence was only observed in the presence of the nonpolar ring-opened *E*-form of the photochromic unit.⁷⁴ The data stored were stable between 223 and 323 K. Furthermore, more than 10⁴ write/read/erase cycles could be performed with only a minor loss in information (Figure 25.19).⁶⁷

FIGURE 25.18 Monomers **42**, **43** for the synthesis of polymers for optical recording media.

FIGURE 25.19 Energy transfer dyad **44** consisting of a 2-indolylfulgimide and a covalently attached strongly fluorescing oxazine dye.

25.5 Fulgimide Architectures for Molecular Electronics

Novel technologies in opto- and bioelectronics have produced a strong interest in new functional modules. For example, photoswitchable organic molecules are of interest for using light as input and output signal between connected chromophores within a logic gate. However, for nano- and optoelectronic devices, immobilization of system modules on metals and semiconductors is essential for future applications. Recent results in these areas directed toward the design of functional modules containing fulgimides are covered in this section.

25.5.1 Photoswitchable Energy Transfer Systems

Port et al. investigated a photoswitchable donor-switch-acceptor energy transfer system **45** (triad) containing a photochromic fulgimide as the switching unit, an anthracene donor group, and a coumarin acceptor group.^{101,102} The intramolecular energy transfer was found to depend upon the isomeric configuration of the photochromic fulgimide, thus, by photoinduced ring-closure and ring-opening of the fulgimide switching unit, the intramolecular energy transfer was switched on and off (Figure 25.20).

A covalently linked 2-indolylfulgimide was applied in order to control the generation of a porphyrin excited state¹⁰³ on route to a molecular triad consisting of a porphyrin linked to two photochromic compounds, a 2-indolylfulgimide and a dithienylethene.¹⁰⁴ Upon excitation of the isomeric form

FIGURE 25.20 Photoswitchable energy transfer triad **45** containing a fulgimide, an anthracene donor group, and a coumarin acceptor group.

FIGURE 25.21 Energy transfer triad **46** consisting of a porphyrin linked to two photochromic compounds: a 2-indolylfulgimide and a dithienylethene.

FIGURE 25.22 Photoswitchable compound **47** performing logic functions.

of compound **46** containing both photochromic units in their visible light absorbing forms (fulgimide: C-form, diarylethene: closed-form; structure not shown) at 470 nm a two-step singlet energy transfer was observed, first to the porphyrin unit within the dyad and then to the dithienylethene (Figure 25.21).

However, upon ring-opening of the dithienylethene using visible light, the second step was eliminated. The excitation of the fulgimide then resides on the porphyrin and fluorescence of the porphyrin was observed. Four isomeric states of the molecule with different light absorption and singlet energy-transfer properties were characterized.^{103,104} Other concepts toward molecules performing logic functions have also been reported based on the principle of using light as inputs and outputs in combination with photochromic compounds that interact photochemically and photophysically with chromophores attached to their molecular skeleton via appropriate linker strategies, for example, compound **47** (Figure 25.22).¹⁰⁵

25.5.2 Photoswitch-Linker-Conjugates for SAMs on Metal and Semiconductor Surfaces

Chromophore containing self-assembled monolayers (SAMs) on metal or semiconductor surfaces are promising research fields toward the development of materials with novel optical and electronical

FIGURE 25.23 Photochromism of a fulgimide-linker-conjugate **50**, and molecular structures of the fulgide and fulgimide precursors **48**, **49**.

properties. However, π -aggregation between chromophores of dye-containing SAMs is a known problem that can dramatically change the chromophore properties. Linkers with a tetrahedral shape have been developed to control the chromophore to surface distance and also to minimize the lateral interaction among chromophores within the SAM. More recently, this concept was applied to photoswitchable chromophores.^{106,107} In the fulgimide series the preparation of an indolylfulgimide adamantane linker conjugate with nitrile anchoring groups was reported.⁸³ To maintain the attachment of fluorescence dyes to the imide functionality of fulgimides, the 6-position on the indole ring was chosen for the attachment of the tripodal linker system with an adamantane core. Furthermore, the 6-position seemed to be ideal in light of the previously observed effects upon placement of an electron-donating substituent in 5-position, for example, the decrease of the quantum yield of the photoreactions.^{22,41} The indolylfulgimide linker conjugate **50** was synthesized from the 6-bromo-substituted indolylfulgimide **49** and an ethynylene linker precursor by Sonogashira cross-coupling.⁸³ For conjugate **50**, a satisfying molar absorption coefficient was detected in analogy to 3-indolylfulgimides with a methoxy group in 6-position. The molar ratios for the C-form in the photostationary states of **49**, **50** were comparable to Yokoyama's compounds **5** and **30** (Figure 25.23).^{22,41}

26.1 Introduction

Photoenolization reactions have been comprehensively reviewed in 1976 by Sammes (Sammes 1976) and, to some extent, in several more recent reviews and book chapters (Klän and Wirz 2009; Mehta and Kotha 2001; Michalak and Gebicki 1993; Sankaranarayanan et al. 2009; Segura and Martin 1999; Wagner and Klän 2003; Weedon 1990; Yoshioka and Saito 2001). The available kinetic and thermodynamic parameters of keto-enol equilibria in aqueous solution have recently been summarized (Wirz 2010). The present chapter attempts to recapitulate the main features of this remarkable phototransformation focusing on advances made with *o*-alkyl aromatic ketones in the past 20 years. The related photoenolization reactions of nonaromatic ketones and esters are not covered.

In 1961, Yang and Rivas demonstrated that the quinonoid dienol intermediates formed by irradiation of 2-methylbenzophenone were sufficiently long lived to allow for chemical trapping (Yang and Rivas 1961). Mechanistic studies of this reaction by flash photolysis initially led to conflicting results due to the strong overlap of transient absorptions observed in the region of 300–500 nm. The mechanism summarized in Scheme 26.1 for 2-methylacetophenone was put forth in 1977 (Haag et al. 1977; Small and Scaiano 1977). It was consistent with the evidence then available from both flash photolysis and chemical trapping studies and has stood the test of time. It also serves, *mutatis mutandis*, as a blueprint for the reactions of related 2-alkylphenacyl compounds.

The equilibrium between the *syn*- and *anti*-conformers in the ground-state matters, because the rotational barrier increases upon n,π^* excitation, and only the excited *syn*-conformers can abstract the γ -hydrogen atom. Thus, the excited singlet state of the *anti*-conformer undergoes exclusive intersystem crossing (ISC) to the triplet state within a few picoseconds, whereas ISC of the *syn*-conformer competes with photoenolization yielding the (*Z*)-dienol in the ground state through a conical intersection (Klän and Wirz 2009). The excited triplet ketones undergo adiabatic H-atom transfer to yield the triplet enol 3E (also called triplet biradical). Quenching studies indicated two kinetically independent excited state precursors of 3E , with lifetimes of on the order of 1 and 10 ns, which were attributed to the

SCHEME 26.1 Mechanism of the photoenolization of 2-methylacetophenone.

syn- and *anti*-conformers of the triplet ketone, respectively (Haag et al. 1977). When the triplet pathway is completely suppressed using high concentrations of a triplet quencher such as piperylene, only the (*Z*)-dienol is formed via the excited singlet state of the *syn*-conformer. The structure of the triplet enol ^3E has not been established. Least-motion H-transfer from the *syn*-triplet ketone would lead to a *syn*-conformer of ^3E that, upon ISC to the ground state, should yield the (*Z*)-dienol. From the fact that both the (*Z*)- and the (*E*)-dienol are formed via ^3E , we must conclude that either the ketyl group is rotated out of plane in the relaxed geometry of ^3E or that two near-planar *syn*- and *anti*-conformers of ^3E are rapidly equilibrated prior to ISC, as shown in Scheme 26.1.

The short-lived ground-state (*Z*)-dienols (*o*-xylylenols or α -hydroxy-*o*-xylylenes) revert to the starting 2-alkylphenyl ketone via 1,5-sigmatropic hydrogen transfer. Their lifetimes are strongly solvent dependent. Those of the (*Z*)-dienol formed from 2-methylacetophenone range from <20 ns in cyclohexane to 160 μs in hexamethylphosphoramide (HMPA), a strong hydrogen-bond acceptor solvent (Haag et al. 1977). Hydrogen bonding of the hydroxyl group thus strongly retards intramolecular back transfer. In contrast, reketonization of the (*E*)-dienols requires intermolecular proton transfer that may occur either by protonation of the methylene group by a general acid or by proton transfer from the enol to the solvent or to a general base, followed by carbon protonation of the dienol anion. The resulting long lifetime of the (*E*)-isomers in dry solvents allows for thermal conrotatory ring closure to give benzocyclobutenols, or they can be trapped by diverse dienophiles such as alkenes, alkynes, or carbonyl compounds in a stereospecific [4 + 2] (Diels–Alder) cycloaddition reaction (Scheme 26.2). Endoperoxides are formed mostly by spin-allowed trapping of the triplet enol ^3E by triplet oxygen (see Section 26.4); they may also be formed when the ground-state dienols encounter singlet oxygen that was generated by oxygen quenching of the triplet ketones or of the triplet enol ^3E (Redmond and Scaiano 1989).

Irradiation of 2-alkylphenacyl compounds in alcohols deuterated on oxygen or in D_2O may lead to isotopic exchange at the alkyl group via the dienols (Scheme 26.2). This will always be the case with (*E*)-dienols, which reketonize by protonation through the solvent. However, ionization of (*Z*)-dienols, which are weak acids ($\text{p}K_{\text{a}} \approx 8$), will generally be slower than intramolecular 1,5-H transfer; the lifetime of the (*Z*)-dienol formed from 2-methylacetophenone is 1 μs in neutral water (Haag et al. 1977). Therefore, isotopic exchange via the (*Z*)-dienols will occur only in the presence of sufficient amounts of acid, base, or buffer to promote isotopic exchange with the solvent. A remarkable finding reported by Gebicky and coworkers (Gebicky et al. 1992; Marcinek et al. 1992) is that radiolytic ionization 2-methylacetophenone in cryogenic matrices yields the corresponding dienol radical cations as the thermodynamically stable tautomers.

SCHEME 26.2 Reactions of the photoenols.

Hydrogen abstraction by excited ketones is not restricted to the γ -position; preference for γ -abstraction is mostly of entropic origin. δ -Hydrogen abstraction competes when it is energetically preferred or when γ -hydrogens are absent (Wagner and Klan 2003; Wagner et al. 1990, 1995). The intrinsic preference for γ - over δ -hydrogen abstraction has been estimated as 20:1 (Wagner et al. 1972). Even ε -hydrogen abstraction has been observed in special circumstances (Carless and Fekarurhobo 1984; Meador and Wagner 1985; Wirz 1974; Zhou and Wagner 1989). Cyclization of the resulting 1,5- and 1,6-biradical intermediates yields five- and six-membered rings, respectively.

The involvement of H-atom tunneling in photoenolization has been investigated by several research groups. The kinetics for photoenolization have been studied extensively in *o*-methylbenzophenone and *o*-methylacetophenone (Das et al. 1979; Findlay and Tchir 1976; Garcia-Garibay et al. 1996; Haag et al. 1977; Ito et al. 1980; Scaiano 1980; Tseng 1976; Wagner and Chen 1976; Wagner et al. 1992), but the kinetics are complicated by conformational flexibility. More recent work has, however, focused on studying H-atom tunneling in molecules such as *o*-methylantrone (**1**, **2**) and *o*-methyltetralone (**3**) derivatives (Gamarnik et al. 1998; Garcia-Garibay et al. 1994, 1995; Gritsan et al. 1991; Johnson et al. 1996; Johnson and Garcia-Garibay 1999). These compounds are rigid and require only a small conformational change to make photoenolization possible. In methylcyclohexane, the lowest energy triplet ketone in *o*-methylantrone has a n, π^* configuration and it undergoes photoenolization even at cryogenic temperatures. Since the Arrhenius plot obtained for the triplet ketone abstracting a D-atom from deuterated *o*-methyl group was nonlinear and large isotope effects were observed, the authors concluded that the triplet ketone undergoes a temperature-independent D-atom tunneling between 18 and 30 K with rate of $2 \times 10^3 \text{ s}^{-1}$ (Garcia-Garibay et al. 1995).

In comparison, the lowest triplet ketone in *o*-methylantrone has a π, π^* configuration in 2,2,2-trifluoroethanol and its phosphorescence lifetime showed a large isotope effect (Gamarnik et al. 1998), indicating that the π, π^* triplet ketone also undergoes H-atom tunneling at low temperature. Furthermore, by measuring the secondary α isotope effect for *o*-methylantrone, Garcia-Garibay and coworkers were able to determine that the width of the transition state barrier affects the rate of H-atom tunneling (Campos et al. 2005). Johnson et al. determined that the different sublevels of the triplet ketone in *o*-methyltetralone react with different tunneling rates (Johnson and Garcia-Garibay 1999).

Johnson et al. studied photoenolization in 6,9-dimethylbenzosuberone (**4**) at cryogenic temperatures and found that the rates of H- and D-transfer from the *o*-methyl group were nearly the same (Johnson et al. 2001). The authors theorized that the rate-limiting step for photoenolization in 6,9-dimethylbenzosuberone is given by isotope-independent skeletal motions, or, in other words, vibrationally assisted tunneling.

Several theoretical calculations have been done to further verify that H-atom tunneling is involved in the photoenolization of *o*-methylantrones and *o*-methyltetralones (Moreno and Lluch 2007; Smedarchina et al. 1994) as well as in some more flexible systems (Arnaut et al. 1984; Barroso et al. 2010; Rao and Chandra 1996; Sengupta and Chandra 1994).

26.2 Cyclization Reactions

When the *o*-alkyl (benzylic) position bears a substituent, four xylylenol isomers are possible (Scheme 26.3). Wagner and coworkers suggested that the geometry of the lowest triplet enol 3E determines which xylylenol isomers are formed (Sobczak and Wagner 1998; Wagner et al. 1998). This assumed that the triplet state lifetime is sufficiently long to allow structural equilibration, the twisted ends of the system rotate in both directions when collapsing to the ground state, and the population of (*Z,Z*)- and (*E,Z*)-isomers is suppressed when the R/R' substituents are large.

Not only 2,6-dialkylphenyl ketones (Sammes 1976) (e.g., **5**, (Wagner et al. 1991)), but also simple *o*-alkylphenyl ketones can form (*E*)-cyclobutenols efficiently upon irradiation (Scheme 26.4). Wagner and coworkers have shown that the acetophenone derivatives **6** give the benzocyclobutenols **7** nearly

SCHEME 26.3 Formation of the xylylenol stereoisomers.

**SCHEME 26.4** Formation of (*E*)-cyclobutenols.

exclusively when irradiated at >290 nm (Wagner et al. 1991, 1998). A single diastereomer with the (*E*)-configuration was formed in all cases. Heating at 80°C quantitatively converted **7** into the starting acetophenones, which invalidates the GC analyses used in some previous studies (the (*Z*)-isomers are thermally stable (Arnold et al. 1974b)).

There has been some controversy whether cyclobutenols are formed from the photoenol intermediates or directly from the triplet biradicals ^3E . The high-yield production of previously undetected (*E*)-cyclobutenols, the diastereoselectivity of cyclobutenol cyclization, and trapping experiments were sufficient evidence for Wagner and coworkers to be convinced that only conrotatory cyclization of (*E*)-enols leads to cyclobutenols (Scheme 26.5, path (a)) (Wagner et al. 1991, 1998). In contrast, Ito and collaborators proposed in the 1980s (Ito et al. 1980, 1981) and later asserted (Ito et al. 1998) that excitation of 2,4,6-triisopropylbenzophenone leads to a “direct” cyclization of the triplet biradical (after ISC) both in solution and the solid state (Scheme 26.5, path (b)).

In addition, Ito and coworkers recently investigated the photocyclization of the 2,4,6-triethylbenzophenone derivatives **8** both in the solid state and in solution (Scheme 26.6) (Ito et al. 2009). The authors conclude that cyclobutenol is formed via conrotatory cyclization of the (*E*)-enol in solution, while “direct cyclization” of the photoenol intermediates is said to be important in the solid state and in sterically hindered ketones. The formation of the indanol (**9**) and (*Z*)-cyclobutenol (*(Z)*-**10**) derivatives were attributed to the topochemical (least motion) principle.

In our view, there is no unequivocal evidence for a distinction between paths (a) and (b) in these reactions (see Scheme 26.5). Adiabatic cyclization of ^3E to form the cyclobutenol triplet can be ruled out on energetic grounds. Thus, ISC must occur in the triplet biradicals, $^3\text{E} \rightarrow ^1\text{E}$, as is assumed by Ito and coworkers.

**SCHEME 26.5** Formation of (*E*)-cyclobutenols from the triplet biradical.

SCHEME 26.6 Photocyclization in the crystalline state.

The nascent singlet biradical ^1E is in fact nothing but the ground-state (*E,E*)-enol **E**, if, presumably, in a somewhat distorted geometry. The claim that “the singlet biradical [^1E] can spontaneously lead to the cyclobutenol without any activation energy” (Ito et al. 1980) is debatable.

Cyclobutenols can be utilized in organic synthesis (Mehta and Kotha 2001). These strained compounds are not very stable; they are sensitive toward acids and bases, which possess limitations for many practical applications. Their thermal conrotatory ring opening leads to the corresponding *o*-xylylenes (*o*-quinodimethanes) that can undergo various cycloaddition reactions (Segura and Martin 1999); cyclobutenols can also be converted into heterocyclic aromatic compounds by reaction with electrophiles (Fitzgerald et al. 1992, 1994a,b), undergo a thermal interconversion of the diastereomers (Kawata et al. 2000) or other transformations (Iida et al. 1999, 2000; Takahashi et al. 1996).

In the past two decades, several examples of the photochemical preparation of cyclobutenols for synthetic purposes were reported. Stereoselective photocyclization of 2-(methoxymethyl)benzophenones (**11**) was shown to give cyclobutenols in >90% yields, which served as precursors for the synthesis of lignans via additional hydrogenation and cycloaddition steps (Scheme 26.7) (Coll et al. 1992).

An interesting twofold photoenolization reaction in *o*- (**12a**) and *p*-dicarbonyl-substituted benzenes (**12b**) leading to the formation of the benzocyclobutenol derivatives **13** (e.g., [*anti*-**13a**]/[*syn*-**13a**] = 1.7 and 1 for R = Ph and benzyl, respectively) was reported by Moorthy and Samanta (Scheme 26.8) (Moorthy and Samanta 2007). The products were obtained in high chemical yields (40%–91%) and were sufficiently stable to be purified by column chromatography. The cyclization was regioselective; the hydrogen was always abstracted from the methyl group in *para* position to the second carbonyl group. Interestingly, only such sterically congested (permethylated) diketones gave bis-benzocyclobutenols. The authors implied that the steric hindrance between the methyl group and the OH group of the photoenol promotes cyclization. In addition, the tandem photoenolization/Diels–Alder cycloaddition reaction (see also later in the text) of **14** was shown to give the adduct **15** in high yields.

2-Alkylphenyl-1,3-dicarbonyl compounds (Yoshioka et al. 1990, 1991) and 3-hydroxy/3-acetoxy-1-alkylphenyl ketones (Yoshioka et al. 1993, 1997) also undergo cyclization to benzocyclobutenols via a photoenolization step. The course of the reaction of **16** was found to depend on the bulkiness of the ester group (Scheme 26.9) (Saito et al. 1998).

Interestingly, several cyclobutenol derivatives have been reported to form in high yields by solid state irradiation of benzaldehyde derivatives (Moorthy et al. 2001a,b; Sarkar et al. 2000). For example, Moorthy et al. reported that the benzaldehyde **17** forms cyclobutenol selectively in the solid state, whereas the benzaldehyde derivatives **18** yield a mixture of the cyclobutenol isomers **19a** and **19b** in

SCHEME 26.7 Stereoselective photocyclization of 2-(methoxymethyl)benzophenones.

SCHEME 26.8 Photoenolization reaction of *o*- and *p*-dicarbonyl-substituted benzenes.

SCHEME 26.10 Reactions of substituted benzaldehydes.

high (82%–100%) yields (Scheme 26.10) (Moorthy et al. 2001b). Furthermore, Moorthy and coworkers were able to use crystal engineering to observe dicyclobutenols from solid state irradiation of iso- and terephthalaldehyde (Moorthy et al. 2003). Generally, formation of cyclobutenols in the crystalline phase results in better yields than that in solution. The benzaldehyde derivatives **20** display solid state photochromism and do not form cyclobutenols (Scheme 26.11) (Moorthy et al. 2001b). More specifically, when crystals of **20** are exposed to light, they turn deep red, and the color persists anywhere from seconds to hours. The authors concluded that the red color was due to formation of (*E*)-photoenols, which do not cyclize to form cyclobutenols, but rather decay by reforming the starting material. The authors

SCHEME 26.11 Solid-state photochromism of **20**.

SCHEME 26.12 Intramolecular H-atom bonding in substituted pyridine-3-carboxaldehydes.

theorized that (*E*)-photoenols stabilized by intramolecular H-atom bonding (Scheme 26.11) are more stable than the corresponding cyclobutenols, therefore, no cyclization was observed. They supported their theory by AM1 calculations, which indicated that the benzaldehyde derivatives (**20**), exhibiting solid state photochromism, formed (*E*)-photoenols that are more stable than the corresponding cyclobutenols. Formation of cyclobutenols in the solid state is not limited to benzaldehyde derivatives. Mal et al. demonstrated that pyridine-3-carboxaldehydes derivatives such as **21**, which have their (*E*)-photoenols stabilized either by intramolecular H-atom bonding or electron-donating substituents, did not yield cyclobutenols in the solid state but exhibited photochromism (Scheme 26.12) (Mal et al. 2003). It supported an assumption that the solid state photochromism is due to long-lived (*E*)-photoenols that are prohibited from undergoing electrocyclic ring closure to form cyclobutenols. In addition, Ito et al. reported that solid state photolysis of some triisopropylbenzophenone derivatives yields cyclobutenols (Ito et al. 1998), whereas solid state irradiation of triethylbenzophenone derivatives results in formation of indanols, presumably via an intramolecular δ -H-atom abstraction (Ito et al. 2009).

26.3 Trapping of Ground-State Oxygen

Oxidation products are frequently observed when photoenolization reactions are carried out in aerated solution and in some cases cyclic peroxides have been isolated (Arnold et al. 1974a; Henderson and Ullman 1965; Yates et al. 1968). Several mechanisms have been considered: (i) trapping of the dienols by ground-state oxygen ($^3\text{O}_2$), (ii) trapping of the dienols by singlet oxygen ($^1\text{O}_2$) that was generated by oxygen quenching of the triplet ketones or the triplet enol ^3E (Redmond and Scaiano 1989), and (iii) trapping of ^3E by $^3\text{O}_2$. Reactions (ii) and (iii) are spin-allowed [4 + 2] Diels–Alder-type additions and may be close to diffusion controlled (Haag et al. 1977; Redmond and Scaiano 1989), whereas reaction (i) is inhibited by a spin barrier and is much slower. The rate constant for the reaction of the (*E*)-dienol of 2-methylacetophenone with oxygen is $2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ (Lutz et al. 1973).

Sammes and coworkers (Arnold et al. 1974a) have isolated the peroxide **22** (Scheme 26.13). In this case, only the (*Z*)-dienol can be formed, which has a submicrosecond lifetime (Haag et al. 1977) under

SCHEME 26.13 Trapping of the dienols by ground-state oxygen.

SCHEME 26.14 Trapping of the biradicals **25** and **28** with oxygen.

SCHEME 26.15 Rearrangement of a cyclic peroxide intermediate.

the experimental conditions used by Sammes. Hence, reactions (i) and (ii) can be ruled out and the peroxide formation must be attributed to path (iii), trapping of the triplet enol 3E by 3O_2 , as was originally suggested by Sammes.

Furthermore, Ito et al. showed that irradiation of solid **23** turns the crystal blue. When the irradiated crystals are dissolved in air-saturated solvents, a small amount of the cyclic peroxide **24** is formed (Ito et al. 1998). Ito et al. hypothesized that **24** was formed by trapping of the biradical **25** with oxygen (Scheme 26.14). Similarly, Pika and coworkers demonstrated that irradiation of **26** in air- and oxygen-saturated solutions resulted in **27** by trapping of **28** with oxygen, followed by intramolecular lactonization (Pika et al. 2003). Furthermore, irradiation of **26** in thin films permitted the same reaction.

Most cyclic peroxides are not stable and rearrange to form various carbonyl products. For example, the irradiation of the diketone **29** (Scheme 26.15) yields a peroxide intermediate, which dehydrates into the tricarbonyl product **30** to give the isobenzofuranone derivative **31** (Saito et al. 1998; Yoshioka et al. 1995).

Similarly, irradiation of **32** in oxygen-saturated solutions leads to the peroxide **33**, which dehydrates to form **34** (Scheme 26.16) (Konosonoks et al. 2005). Additionally, irradiation of **34** results in intramolecular H-atom abstraction to form **35**, which lactonizes to **36**. The photooxidation of **29** and **32** is similar to that reported by Pfau et al. who studied photooxidation of *o*-methylbenzophenone (Pfau et al. 1983).

26.4 Cycloaddition Reactions

Ground-state *o*-xylylenes that live long enough can undergo the Diels–Alder cycloaddition with alkenes, alkynes, carbonyl compounds, or other substrates. They can be produced by thermolysis of the corresponding benzocyclobutenes (Segura and Martin 1999) or photochemically (Sammes 1976; Weedon 1990). Before 1990, the stereoselective cycloadditions of *o*-xylylenes with alkenes was introduced in the synthesis of chiral tetralines (e.g., Arnold et al. 1973; Macdonald and Durst 1986; Quinkert et al. 1981, 1982). In the past two decades, many examples demonstrated that this reaction is practical to synthesize

SCHEME 26.16 Photooxidation of **32**.

tetrahydronaphthalene derivatives. Charlton and coworkers published a series of accounts of the asymmetric Diels–Alder reactions of photochemically formed *o*-xylylenols with various acrylate, fumarate, or lactate esters (Charlton and Koh 1990, 1992; Charlton and Maddaford 1993; Charlton et al. 1989a,b, 1990, 1993). For example, the fumarate **37** was found to react with the photoenol **38**, generated from the aldehyde **39** with very high diastereoselectivity (>90% de) (Scheme 26.17) (Charlton et al. 1990). The product **40**, obtained from **41** in four subsequent steps, is an analogue of podophyllotoxin, known by its strong mitotic activity. In a similar fashion, Kraus and coworkers also demonstrated usefulness of the tandem photoenolization/Diels–Alder cycloaddition reactions in the synthesis of biologically active compounds, such as podophyllotoxin (Kraus and Wu 1992), an anthraquinone derivative G-2N (Kraus and Zhao 1995, 1996), pleurotin (Kraus and Chen 1991a; Kraus et al. 1993), or 4-deoxyaklavinone (Kraus and Chen 1991b).

It was also shown that a methyl lactate derivative adds to the *o*-xylylenol **42** to produce preferentially an unexpected *exo* product (**43**) in 77% yield (Scheme 26.18; only one enantiomer shown). The calculations revealed that the stereoselectivity is related to the hydrogen bonding between the hydroxy group of the enol and the ester (**44**) carbonyl group (Charlton and Maddaford 1993). Narasaka and coworkers showed that phenylboronic acid **45** can be used as a template to trap a short-lived *o*-xylylenol photochemically formed from 2-tolualdehyde (**46**) and methyl 4-hydroxy-2-butenate (**47**) to allow formation

SCHEME 26.17 Diels–Alder reactions of photochemically formed *o*-xylylenols.

SCHEME 26.18 Addition of an olefin to the *o*-xylenol.SCHEME 26.19 Addition of an olefin to the *o*-xylenol in the presence of phenylboronic acid.

of the Diels–Alders products (Scheme 26.19) (Shimada et al. 1993). Some other derivatives of 2-alkylbenzaldehydes, such as 2-formylbenzamides (Kessar et al. 1993) or *o*-formylbenzyltrialkylstannanes (Sano et al. 1999), were also reported to produce tetrahydronaphthalen-1-ol cycloaddition products when irradiated in the presence of various dienophiles.

The total synthesis of hamigerans, naturally occurring cytotoxic substances, was accomplished by the Diels–Alder reaction of photochemically generated photoenols from substituted benzaldehydes (Nicolaou et al. 2001a,b, 2004; Nicolaou and Gray 2004). In one example, both (*E*)- and (*Z*)-isomers of **48** were photochemically converted to the corresponding *o*-xylenols that subsequently underwent intramolecular cycloaddition to give the tetralines **49** in 78%–91% yields (Scheme 26.20) (Nicolaou et al. 2004). Irradiation of (*E*)-**48** led to *syn*- and *anti*-**49** in a concentration ratio of 25:1, whereas irradiation of (*Z*)-**48** gave a reverse ratio (1:3). These results were found to depend on the photostationary state concentrations of the isomers of **48**, which interconvert via *E*–*Z* photoisomerization. The authors concluded that only a single diastereomer is formed in both cycloaddition reactions because the repulsion between the methyl and hydroxymethyl groups is minimized when they are *anti* to one another in the transition state (represented by the intermediate **50**).

Diels–Alder trapping of *o*-xylenols was successfully utilized to synthesize some other oligocyclic compounds. Bicyclic aldehydes **51** (Connolly and Durst 1997), a bicyclic oxyquinoline-5-aldehyde **52** (Grosch et al. 2003, 2004), 2-methylbenzaldehyde (**53**) (Tsuno and Sugiyama 1991, 1992, 1994) (Scheme 26.21), and the diketones **54** and **55** (Ilhan et al. 2006) (Scheme 26.22) were reported to form the corresponding photoenols upon irradiation and subsequently the cycloaddition products (the chemical yields are shown in the schemes). In addition, two interesting recent applications can be found in the literature. Production of photoenol from 2-methylbenzophenone attached to a monolayer-protected gold cluster

SCHEME 26.20 Synthesis of hamigerans using a photoenolization step.

SCHEME 26.21 Diels-Alder trapping of *o*-xylenols.

and the subsequent Diels-Alder reaction with alkene or alkyne dienes was described by Workentin and coworkers (Kell et al. 2003). Nishimura and coworkers reported trapping of *o*-xylenols, photochemically formed from various aromatic aldehydes and ketones, by [60]fullerene (Nakamura et al. 2002). Meador and coworkers have recently used Diels-Alder trapping of (*E*)-photoenols as an alternate route to form photocured polymers (Meador et al. 2007; Tyson et al. 2005).

SCHEME 26.22 Diels–Alder trapping of *o*-xylenols formed from aromatic diketones.SCHEME 26.23 Diels–Alder trapping of *o*-xylenols formed from benzaldehydes.

Moorthy et al. demonstrated that solid state irradiation of several benzaldehyde derivatives (**56**, Scheme 26.23) results in formation of hemiacetals in excellent yields (88%–100%) (Moorthy et al. 2004). The authors speculated that these hemiacetals are formed via (*E*)-photoenols undergoing the Diels–Alder cycloaddition with its precursor. They also proposed that intermolecular H-atom abstraction by the triplet ketone might be responsible for formation of the hemiacetals.

26.5 Other Addition Reactions

In the absence of trapping agents, *o*-xylenols dimerize to form the hemiacetal products (Findlay and Tchir 1974). Durst and coworkers showed that irradiation of the 2-methylbenzoyl cyanide **57** (Connors and Durst 1992) or its derivatives (Connors et al. 1996) results in the formation of the dimers **58** (80% yield for R = H) (Scheme 26.24). These products can be converted to substituted naphthols or isoquinolones by reactions with various nucleophiles.

SCHEME 26.24 Dimerization of *o*-xylylenols.

SCHEME 26.25 Photoreactions of 2-methylbenzaldehyde.

SCHEME 26.26 Trapping of diphenylcarbene by *o*-xylylenol.

Griesbeck and Stadtmüller reported that while irradiation of 2-methylbenzaldehyde in benzene gives **59**, a mixture of the hemiacetal **60** and its open form **61** (the combined yield was 91%) is formed in the presence of 1,1,1-trifluoroacetone (Scheme 26.25) (Griesbeck and Stadtmüller 1993).

It was also reported that short-lived diphenylcarbene ($\tau \sim 1 \mu\text{s}$), generated photochemically from diphenyldiazomethane, can be trapped by a longer lived photoenol of 2-methylbenzophenone under laser-jet conditions (Scheme 26.26) (Wilson et al. 1987, 1992). All three products (**62**–**64**) are the trapping adducts; the diphenylmethylether **64** could also be a coupling product of benzocyclobutenol with the carbene. The course of reactions was suggested to depend on the diphenylcarbene multiplicity.

26.6 Photodienols to Release Nucleophiles

When leaving groups are present in an appropriate position, the photoenol intermediates can undergo elimination reactions. The leaving groups on the α -carbon of 2-methylphenacyl compounds are released efficiently and in high yields (up to 96%) to form the indanone derivatives **65** in non-nucleophilic solvents (Scheme 26.27). The acetophenone derivatives substituted on the *o*-methyl group **66** can be produced in the presence of a nucleophile (such as methanol). This reaction, introduced by Bergmark (phenacyl chlorides and bromides) (Bergmark 1978; Bergmark et al. 1985), was later shown to be applicable in the field of photoremovable protecting groups (Pelliccioli and Wirz 2002). Klán, Wirz, and coworkers demonstrated that the 2,5-dimethylphenacyl (DMP) group can be used to protect carboxylic acids (Klán et al. 2000; Ruzicka et al. 2002; Zabadal et al. 2001), phosphates, sulfonates (Klán et al. 2002), alcohols (as carbonates) (Literak et al. 2005), as well as amines (as carbamates) (Kammari et al. 2007). It was established that only moderately good leaving groups can be released within the photoenol lifetime. Investigations by laser flash photolysis indicated that irradiation produces all expected intermediates, the short-lived triplet enol 3E , and two longer lived photoenols assigned to (*Z*)- and (*E*)-xylylenols in the ground state (see also Scheme 26.3) (Klán et al. 2002; Literak et al. 2005; Zabadal et al. 2001). The (*E*)-xylylenols were found to have sufficient lifetime to release carboxylates, while the (*Z*)-xylylenols recovered the starting ketone. In contrast, the chloride anion, an excellent leaving group, was found to be released also from the (*Z*)-xylylenol (Pelliccioli et al. 2001). Constrained ketones, such as 1-oxoindan-2-yl or 1,3-dioxoindan-2-yl moieties, which are either nonreactive (see Section 26.1) or form only short-lived (*Z*)-xylylenols, cannot be used as photoremovable protecting groups (Literak et al. 2008).

To overcome the problem that the DMP chromophore cannot serve as a photoremovable group for alcohols or amines, which are relatively poor leaving groups, they were attached through carbonate (Literak et al. 2005) or carbamate (Kammari et al. 2007) linkers, respectively, possessing similar leaving group ability to that of a carboxylate. For example, the galactopyranosyl carbonate **67** was found to release the corresponding alcohol **68** in >70% chemical yields (Scheme 26.28) (Literak et al. 2005). Other authors also reported photochemical applications of the *o*-methylphenacyl group. Wang and coworkers used this moiety in polymer-supported synthesis (Du et al. 2005), and Park and Lee showed that this group can be part of new photoresponsive polymers (Park and Lee 2008).

When the acetyl or benzoyl group is attached to the α -position of *o*-methylacetophenone, the photoreaction results in efficient decarboxylation (Scheme 26.29) (Sobczak and Wagner 2002). The authors proposed that an intramolecular proton transfer step is essential for the reaction.

In a different way, Wirz (Pelliccioli and Wirz 2002) and later Banerjee and their coworkers (Atemnkeng et al. 2003) proposed a new photoremovable protecting group based on the 1-[2-(2-hydroxyalkyl)phenyl]ethanone moiety **69** (Scheme 26.30). Here the leaving group is attached in the β -position of

SCHEME 26.27 2-Methylphenacyl compounds as photoremovable protecting groups.

SCHEME 26.28 Release of alcohols using a carbonate linker.

SCHEME 26.29 Decarboxylation of substituted phenylacetic acid.

SCHEME 26.30 1-[2-(2-Hydroxyalkyl)phenyl]ethanone moieties as photoremovable protecting groups.

o-ethylacetophenone. This relatively inefficient photoreaction was shown to release the carboxylic acid in 70%–85% isolated yields (Atemnkeng et al. 2003).

The same mechanism operates in 5-(ethylen-2-yl)-1,4-naphthoquinone, a photoremovable protecting group that absorbs up to 405 nm and provides fast and efficient release of bromide or diethyl phosphate ($\Phi = 0.7$ in aqueous solution) (Kamdzhilov and Wirz 2007). The blue photoenol is formed in the ground state within 2 ps of excitation and with a quantum yield of unity (Chiang et al. 1997).

Photoenols can also be used for elimination reactions via intramolecular lactonization. More specifically, elimination can be initiated by intramolecular lactonization of the hydroxyl group of an (*E*)-photoenol. For example, Pika et al. showed that irradiation of **70** gives the corresponding (*Z*)- and (*E*)-photoenols, and that the (*E*)-photoenol undergoes intramolecular lactonization to release an alcohol (Scheme 26.31) (Pika et al. 2003). The elimination or release of the alcohol takes place in various solvents as well as in thin films. This reaction is not quenched by molecular oxygen because the peroxide formed by trapping the biradical **71** with oxygen undergoes intramolecular lactonization to release the alcohol moiety.

In comparison, Konosonoks et al. found that irradiation of **72** in aprotic solvents did not yield any products (Scheme 26.32) (Konosonoks et al. 2005). Transient spectroscopy showed that the photoenols formed were considerably shorter lived than the photoenol obtained from **70** (Scheme 26.31). Thus, the

SCHEME 26.31 Elimination reactions via intramolecular lactonization of an (*E*)-photoenol.

SCHEME 26.32 Nonproductive photochemistry of 72.

SCHEME 26.33 (*E*)-Photoenol lactonization to release an alcohol.

authors concluded that intramolecular lactonization was not efficient enough to compete with the reketonization of the (*E*)-photoenol from 72.

Similarly, the ketone 73 forms (*E*)- and (*Z*)-photoenols upon exposure to light, while only the (*E*)-photoenol undergoes lactonization to release an alcohol to form 74 (Scheme 26.33) (Muthukrishnan et al. 2010). However, irradiation of 75 does not lead to any photoproducts because it only forms a

SCHEME 26.34 Photochemical closure reactions of **77**.

(*Z*)-photoenol that decays back to the starting material. Intramolecular pseudo H-atom bonding and rotation barrier prevent **75** from ISC to form the (*E*)-photoenol. The major difference between the benzophenone **70** and the butyrophenone **73** is flexibility of an alkyl chain in **73**. This presumably allows the (*E*)-photoenol formed from **73** to release its alcohol moiety faster than **70**.

Various synthetically interesting functionalized indan-1-ones have been produced using photoenolization reaction that involves the release of the leaving group from the α -position of an *o*-methylacetophenone derivative. Berkessel and collaborators used this reaction to study the cyclization of 4'-benzophenone-substituted nucleoside derivatives as models for ribonucleotide reductases (Lehmann et al. 2000). Wessig and coworkers used this concept for the preparation of various 1-indanone derivatives (Wessig et al. 2004), and for the total synthesis of two sesquiterpene indane derivatives, pterosine B or C (e.g., **76**, Scheme 26.34), in which the key step is the photochemical closure reaction of **77** (Wessig and Teubner 2006). Klán and coworkers showed that irradiation of a 4,5-dimethoxyphenacyl derivative can lead to an indanone precursor for the synthesis of donepezil, a centrally acting reversible acetylcholinesterase inhibitor used to treat Alzheimer's disease (Pospisil et al. 2008). Interestingly, Park and Ryu have recently reported that irradiation of 2,4,6-trialkylphenacyl benzoates yields the corresponding benzocyclobutenols in addition to the corresponding indanones and benzoic acid (Park and Ryu 2010).

Irradiation of 2-(alkoxymethyl)-5-methyl- α -chloroacetophenones (**78**) was reported by Klán and coworkers to be very sensitive to traces of water in the solvent (Scheme 26.35) (Plistil et al. 2006). While

SCHEME 26.35 Photochemistry of 2-(alkoxymethyl)-5-methyl- α -chloroacetophenones.

SCHEME 26.36 Photochemistry of 2,5-dimethylbenzoyl oxiranes.

3-methoxy-6-methylindan-1-one (**79**) was formed in dry, non-nucleophilic solvents, the isobenzofuran-1(3*H*)-one **80** was isolated as a major photoproduct in the presence of trace amounts of water. It was explained that photoenols produced by irradiation of **78** add water as a nucleophile to form 2-acetyl-4-methylbenzaldehyde (**81**), which is further converted to **82** through a second, singlet state photoenolization process.

Klán and coworkers recently reported that irradiation of the 2,5-dimethylbenzoyl oxiranes **83** results in a relatively efficient ($\Phi = 11\text{--}25$) and high-yielding ($\sim 70\%$) formation of β -hydroxy functionalized indanones that structurally resemble biologically active pterosines (Scheme 26.36). Laser flash photolysis experiments and quantum-chemical calculations provided solid evidence that the indanone photo-products are formed via a photoenolization mechanism (Solomek et al. 2010).

27.1 Introduction

The Paternò–Büchi reaction is one of the most ancient reactions in organic photochemistry (Scheme 27.1). Paternò and Chieffi reported obtaining oxetanes from the photocycloaddition of ketones to olefins in 1909, but this reaction was recognized as an important synthetic reaction only after the work of Büchi [1,2].

After these pioneering works, several reviews cover the enormous number of papers published in this field [3–13]. The synthesis of oxetanes can have a great importance in the development of compounds with relevant biological properties: oxetane ring is present in the scaffold of Taxol® (**1**), an important drug used in the treatment of ovarian cancer [14]; merrilactone A (**2**), a sesquiterpene dilactone with neurotrophic activity [15]; and several antiviral oxetanes, such as **3**, **4**, and **5**, have been described in the literature (Scheme 27.2) [16–18].

27.2 The Reaction

The Paternò–Büchi reaction is a photocycloaddition reaction of a n,π^* carbonyl compound to an alkene in the ground state from either the S_1 or the T_1 state. Frontier orbitals approach can be used to explain the formation of oxetanes. We can observe HSOMO–LUMO interaction in which the half-occupied π^* carbonyl orbital interacts with the unoccupied π^* molecular orbital of an electron-deficient alkene in a parallel configuration and a C,O-biradical is formed. When the LSOMO–HOMO interaction, in which the half-occupied n orbital of the carbonyl O atom interacts with the π -orbital of an electron-rich alkene in a perpendicular conformation, is prevalent, a C,C-biradical is formed [19–22]. The majority of Paternò–Büchi reactions occur from the carbonyl triplet state, which is accessed by an intersystem crossing. Intermediate 1,4-biradicals derived from carbonyl triplets were studied spectroscopically [23–26] and they were trapped by radical quenchers [27–30]. In the reaction between 1,4-dioxene and benzaldehyde, theoretical calculations showed that the only transition able to give the observed transient absorption is that from LSOMO to LUMO (549 nm) and that it is a $\pi \rightarrow \pi^*$ transition; the same result was obtained for the reaction between furan and benzaldehyde [12].

SCHEME 27.1 Paternò-Büchi reaction.

SCHEME 27.2 Naturally occurring or biologically active compounds bearing an oxetane ring.

An approach where the regioselectivity of the reaction was explained considering the hard-soft acids and bases theory has been published and it gave results in agreement with the experimental results [31]. On the other hand, the regiochemistry of the Paternò-Büchi reaction has been explained using an approach considering that atoms arrange themselves so that the obtained molecule reaches the minimum electrophilicity [32].

A theoretical study of the Paternò-Büchi reaction showed that there are two conical intersection points located near the C-C and C-O bonded biradical regions of the ground state. These two conical intersections support a mechanism where the decay from the excited state is accompanied by a geometric rotation of the terminal group, in the case of C-O attack, and by an orbital rotation at the oxygen center, in the case of C-C attack. Furthermore, for C-O attack, the triplet surface must cross the singlet to reach a diradicaloid minimum. For C-C attack, the triplet biradical minimum is located at the same geometry as the conical intersection between the two singlet states, and the efficiency of the intersystem crossing will be determined by the nature of the spin-orbit coupling. Thus, for the triplet, the reaction path can be predicted by the most stable biradical rule [33]. A conformational analysis of the biradicals also appeared [34,35].

A CAS SCF geometry optimization in TZV basis set of the intermediate biradicals showed that the diradical region corresponding to the C-C attack lies about 10 kcal mol⁻¹ lower in energy than the C-O region [36,37]. We have to note that this result is not in agreement with reported experimental results.

The formation of exciplex is used to explain the reaction behavior of simple alkene. However, evidence of mono-electron transfer processes is reported for electron-rich alkenes [38].

The reaction is quite general. 5-Substituted adamantan-2-ones gave the corresponding cycloadducts via the n,π^* excited singlet state, giving a regiospecific reaction without stereoselectivity (the best result was 59:41 in favor of the *anti* isomer) [39–42]. When methyleneadamantane reacted with acetone, the Paternò-Büchi adduct was obtained in only 5% yield [39]. The reaction of biacetyl with benzvalene gave the corresponding adduct, while benzophenone gave as the only product benzene [43]. Ethyl phenylglyoxylate reacted with homobenzvalene to give the corresponding adduct in 70% yield with high stereoselectivity (Scheme 27.3) [44].

SCHEME 27.3 Paternò-Büchi reaction of homobenzvalene with methyl phenylglyoxylate.

A stereoselective behavior has been described in the reaction between benzophenone and cyclooctene. Whereas at -95°C the *cis* adduct was formed in a very high *cis* diastereoselectivity from *cis*-cyclooctene, both diastereoisomers were generated at -20°C . At higher temperatures, the *trans* adduct dominated. The more strained *trans*-cyclooctene gave over a broad temperature range (-80 to $+60^{\circ}\text{C}$) nearly exclusively the *trans* adduct [45,46]. This behavior can be understood considering that triplet ketone can attack the double bond to give two biradical intermediates: the authors suggested that temperature-dependent conformational changes of the biradical compete with the cyclization to the oxetane and the retro cleavage to the *cis*-cyclooctene. The increasing of *trans*-oxetane with the temperature can be due to the activation barrier between two conformers of the biradical intermediate [46].

1-Acetylisatin reacted with styrene and furan derivatives to give stereoselectively the *endo* adduct [47,48]. The reaction of quinones with stilbene derivatives has been described [49,50]. In this case, a charge-transfer absorption band was observed at 480 nm. Time-resolved (ps) absorption spectrum showed an absorption at 480 nm (chloranil anion radical) and a broad band around 760 nm. After 50 ps a transient absorption typical for triplet chloranil at 510 nm was observed. The reaction occurs through selective excitation at 480 nm. Quinones react with diarylacetylene giving a product deriving from the ring opening of a transient oxetene. Time-resolved (ps) absorption spectrum is in agreement with an electron transfer mechanism [51]. In the reaction between 2-chloro-5-methoxybenzoquinone with arylacetylenes, CIDNP experiments are in agreement with a mechanism involving the attack of the triplet quinone on the acetylene to give a biradical intermediate [52]. The same behavior has been observed in the reaction between quinone and quadricyclane and norbornadiene [53,54]. A Paternò-Büchi adduct was found also in the reaction between quinones and acenaphthylene [55].

A reaction between benzophenone and a paracyclophane derivative **6** has been described (Scheme 27.4) [56]. An intramolecular Paternò-Büchi reaction on a paracyclophane derivative **7** has been reported giving the corresponding adduct in quantitative yield (Scheme 27.4) [57].

The Paternò-Büchi reaction can also be applied to other unsaturated systems other than an alkene, such as dienes [4], allenes [58], acetylenes [59], and ketenimines [58]. In the reaction of tetramethylallene with aromatic ketones the main products often resulted from bis-addition of the carbonyl compounds to give dioxaspiroheptanes [60,61]. In the reaction of 1,1-dimethylallene with aliphatic aldehydes, only

SCHEME 27.4 Paternò-Büchi reaction on paracyclophane derivatives.

SCHEME 27.5 Paternò-Büchi reactions on allenes.

the monoaddition products **8** and **9** were obtained, with a low regioselectivity (2:1) (Scheme 27.5) [62]. A higher regioselectivity was obtained using the allene **10** (Scheme 27.5).

27.3 Reactions of Carbonyl Compounds with Enolethers and Enolthioethers

The first oxetane deriving from ethyl vinyl ether and benzophenone was described by Paternò [63]. The reaction between acetone and ethyl vinyl ether in the presence of ultrasounds gave a different mixture of regioisomers than that obtained without the use of the ultrasounds [43].

Substituted pyruvates reacted with 1,3-dioxol **11** to give the *endo* isomer **12** (Scheme 27.6) [64–66]. The observed stereochemical behavior was explained on the basis of the analysis of the conformations of the biradical intermediate [67].

Unsubstituted cyclopropyl enol ethers gave the corresponding oxetane rings. On the other hand, substitution on the cyclopropyl ring induced the formation of oxepanes derived from cyclopropyl ring opening at the level of the biradical intermediate [68]. The enol ether **13** reacts with benzaldehyde giving, after acid hydrolysis, the oxetane **14** with a good diastereoselectivity (Scheme 27.7) [69].

1,2,3-Indanetrione reacts with 2,3-diphenyl-1,4-dioxene to give the oxetane on the carbonyl in 2 position [70]. When 2,3-dimethyl-2-butene is used, a complex mixture of products is obtained [56]. The irradiation of 2,3-dihydrofuran with benzophenone in benzene gave adduct **15** (Scheme 27.8) [71]

By using acetone the adducts were obtained in 52% yield in a 200:1 isomeric ratio [72]. The reaction of 5,5-dimethyl-2,3-dihydrofuran with both aromatic and aliphatic aldehydes gave the corresponding adducts with high *endo* selectivity [73]. When acetaldehyde was used, the adduct was obtained in

SCHEME 27.6 The reaction of a 1,3-dioxol derivative with a substituted pyruvates.

63% yield as a mixture of stereoisomers. The selectivity depended on 2,3-dihydrofuran concentration: this behavior was in agreement with a switch from a triplet mechanism to a singlet mechanism at higher concentration [74–77]. When benzaldehyde was used as carbonyl compounds the adducts were obtained with an overall yield of 98% as a >98:2 regioisomeric mixture. The major isomer is 88:12 *endo/exo* mixture. The reaction showed a good regio- and stereoselectivity (Scheme 27.9) [77–80]. This stereoselectivity was partially lost when benzaldehyde reacts with 2-methyl-2,3-dihydrofuran [78,81].

A change of regioselectivity was observed when the reaction with benzaldehyde was performed in high polar solvent in agreement with an electron transfer mechanism (Scheme 27.10) [74,75].

This reaction is the first example where a spin controlled selectivity is observed [76,82]. In singlet photoreactions, stereoselectivity is often controlled by the optimal geometries for radical–radical combinations, whereas in triplet photoreactions the geometries most favorable for ISC are considered to be of similar relevance. The singlet biradicals should be too short lived to enable rotation about the endocyclic C–O or C–C bonds and therefore, conformation memory effects on the stereochemistry are expected. The geometries in the triplet state can be quite different from the former ones due to differences of the spin–orbit coupling (SOC) values. The lifetimes of many triplet biradical intermediates are definitely high enough to enable bond rotations and the formation of the thermodynamically favored product can be expected because the radical–radical combination step should no longer be influenced by the approach geometry, that is, “memory effects” should be erased due to the relatively long lifetimes. After transition from the triplet to the singlet potential energy surface, immediate product formation is expected. Thus, the ISC is expected to proceed in a concerted fashion with the formation of a new bond or the cleavage of the primarily formed single bond. As a consequence, the stereoselectivity of the Paternò–Büchi reaction is the result of a combination of several rate constants for cyclization versus cleavage reactions.

The biradicals are the direct consequence of the precursor spin and their lifetimes are connected with the mode of spin inversion processes and the mechanism, which leads to the formation of closed-shell products. Benzaldehyde reacts in its triplet state. This way, a triplet biradical is formed as an intermediate. For the formation of the products, intersystem crossing into the singlet manifold is necessary. The most important factor influencing an intersystem crossing for flexible triplet biradicals is spin–orbit coupling. The angle between *p* orbitals at the radical centers is approximately 90° for maximum spin orbit coupling. For the pronounced *endo* selectivity in the reaction between aromatic aldehydes and

SCHEME 27.11 Possible conformations of the 1,4-biradical from the reaction of 2,3-dihydrofuran with benzaldehyde.

2,3-dihydrofuran, we can consider the two biradical conformers **16** and **17** to be responsible, with the alkyloxy substituent localized in a pseudoequatorial position and **16** being more populated because of fewer steric interactions (Scheme 27.11). When a methyl group is present, the increasing *gauche* interactions with the β -alkyloxy substituent lead to a certain concentration of **18** and **19**, again with **18** being preferred because of fewer steric interactions.

Another approach has been used in order to explain regio- and stereochemistry [83]. In fact, theoretical calculations showed that the biradical **20** is more stable than **21** for 1.49 kcal mol⁻¹ (Figure 27.1).

Furthermore, the HSOMO is mainly localized on the aromatic ring and it is extended until the radical carbon. The LSOMO is mainly localized on the dihydrofuran ring. The coupling between the radical carbons in these two orbitals is possible (the atomic orbitals involved can superimpose themselves) only if the *endo* isomer is formed (Figure 27.2) [83].

α - and β -naphthaldehydes, on the contrary, gave high *exo* selectivity. The reaction occurs also in the presence of triplet quenchers, while fluorescence quenching in the presence of dihydrofuran was observed: in this case, singlet excited states are responsible for the high *exo* selectivity [77,84]. Why? The explanation is simple. In this case, the coefficients on the HSOMO and LSOMO allowed the coupling of the radical carbons only if the *exo* isomer is obtained [85].

The stereoselectivity of the reaction between ethanal and 2,3-dihydrofuran was found to depend on the viscosity of the solvent (higher viscosity induces a higher *endo* stereoselectivity) and significant temperature dependence: at room temperature, the *exo* adduct was formed with low selectivity, predominantly through the singlet channel. This selectivity increases with decreasing temperature and reaches an inversion point at -17°C. At this point, the triplet reactivity gains sufficient influence to increase the *endo* selectivity [86].

When 2,3-dihydrofuran derivatives react with α,β -unsaturated carbonyl compounds, 2 + 2 cycloaddition between the olefins occurs [87]. Benzaldehyde reacts with L-ascorbic acid giving a mixture of regioisomeric compounds with *exo* stereoselectivity [50].

FIGURE 27.1 Possible biradical intermediates in the reaction of 2,3-dihydrofuran with benzaldehyde.

FIGURE 27.2 Ring closure reaction in the formation of the *endo* isomer of the adduct between 2,3-dihydrofuran and benzaldehyde.

SCHEME 27.12 Paternò-Büchi reaction of benzophenone with alkenyl sulphides.

The reaction of benzophenone with alkenyl sulphide showed a high regioselectivity (Scheme 27.12) [88]. A similar regioselectivity was obtained when ethyl vinyl ether was used as an alkene with benzaldehyde and benzophenone [89].

27.4 Reactions with Enol Esters, Enol Silyl Ethers, and Enamines

27.4.1 Enol Acetates

High regio- and stereoselectivity (*syn* addition) was observed in the reaction of pentafluorobenzaldehyde with enol acetates [90]. The reaction between a 2,3-thiophenone derivative and vinyl acetate gave the corresponding adduct on a ketonic function in low yields [55].

27.4.2 Silyl Enol Ethers

The reaction between a trimethylsilyl derivative of cinnamyl alcohol and benzaldehyde gave the *trans*-oxetane with high stereoselectivity (Scheme 27.13) [91].

3-(Silyloxy)oxetanes **24** were successfully prepared from silyl enol ethers **23** containing carbon–chlorine, carbon–silicon, or carbon–sulfur bonds (Scheme 27.14) [92,93]. Also ether and ester groups are compatible with the reaction. The presence of alkene moiety is also compatible. When a β -alkyl substituted silyl enol ether is used, *trans*-oxetanes are obtained. This result does not depend on the (*E*)- or (*Z*)-nature of the alkene. The products were obtained with high simple diastereoselectivity (ds 74%–95%) [94].

In the triplet biradical, free rotation leads to highly preferred, sterically least congested conformation. The further reaction pathway of this species includes ISC and an assumed selection step (cleavage versus ring closure) at the singlet 1,4-diradical level, which accounts for the high simple diastereoselectivity at C-2/C-3.

The oxetanes **24** can be converted into the corresponding diols **25** by using hydrogenolysis under Pd catalyst (Scheme 27.15). Acid-sensitive substrates can be protected using Pd(OH)₂ as a catalyst as reported in the reaction of the acetal **26** (Scheme 27.15) [95]. Also LiAlH₄ can be used in order to induce the cleavage of the oxetane ring [96].

The presence of a stereogenic center in the β -alkyl group (as in **28**) induced a facial diastereoselectivity with high diastereoisomeric ratios in some cases (Scheme 27.16) [97].

SCHEME 27.13 Paternò-Büchi reaction of silyl ether of cinnamyl alcohol.

SCHEME 27.14 Paternò-Büchi reaction between enol silyl ethers and benzaldehyde.

SCHEME 27.16 Paternò-Büchi reaction of enol silyl ethers with β -alkyl substituents.

FIGURE 27.3 Diastereoselectivity in chiral enol silyl ethers' reaction with benzaldehyde.

The diastereoselectivity is probably due to the presence of a conformational preference represented in the Figure 27.3. This conformation allows the *Si* attack [96].

In this case a fluoride-promoted cleavage procedure can be used to open the oxetane ring [97]. When the chiral center is in α position low facial diastereoselectivity was observed [98]. The best results were obtained by using both the silyl enol ether 31, which gave the adducts 32 and 33 with a 67/33 d.r. and the compound 34, giving the adducts 35 and 36 in 15/85 d.r. (Scheme 27.17) [98].

The possible synthetic utility of the oxetanes, when in the side chain a removable protecting group is present, has been studied. The possible intramolecular nucleophilic attack on the oxetane ring gave some interesting products [99].

Oxetanes were obtained in low yields in the reaction of 1,2-diketones with trimethylsilyl ketene acetals [100]. Oxetanes can be obtained as a by-product in the reaction of ketene silyl acetals with aromatic carbonyl compounds: in some cases it represents the main product [101]. Cyclic ketene silyl acetals 37

SCHEME 27.17 Stereoselectivity in the Paternò-Büchi reaction of enol silyl ethers.

SCHEME 27.18 Paternò-Büchi reaction of silyl ketene acetals.

reacts with 2-naphthaldehyde to give the corresponding adduct **38**, determined via NMR analysis, while the treatment of the reaction mixture with water gave the aldol-type product **39** with high stereoselectivity (Scheme 27.19). The oxetane was obtained with *anti* stereochemistry [57,102]. The effect of both the solvent and the nature of the silyl group has been examined [52]. Good results were obtained silyl O,S-ketene acetals were used [45]. In particular when the *E* isomer **40** was used only the *trans,trans*-isomer **41** was obtained (Scheme 27.18).

The stereochemical behavior was explained considering the capability of the sulfur atom to coordinate the oxygen atom of the carbonyl compound [45]. The same regio- and stereoselectivity was observed when silyl O,Se-ketene acetals were used [46].

27.4.3 Enamines

N-Acyl enamines **42** and **45** gave the corresponding adducts with high regio- and stereoselectivity (Scheme 27.19) [103–106]. The thermodynamically more stable isomer is obtained [107].

The use of chiral enamines did not give high diastereoselectivity, with the exception of the enamine **47**, which gave the corresponding adduct with 62% *de* (Scheme 27.20) [108,109].

N-Formyl protected oxetanes can be converted into the corresponding *syn*-1,2-amino alcohols through treatment with LiAlH_4 [110]. Alternatively, the treatment of **50** with TFA gave the oxazolidinone **51**, which can be converted into the corresponding *anti*-1,2-amino alcohol **52** (Scheme 27.21) [104,110].

This approach has been used in the synthesis of both (\pm)-oxetin [111] and (+)-preussin [112,113].

We have also reactions on alkenes bearing both electron-donating groups (nitrogen atoms) and electron-withdrawing groups. 2-Morpholinopropenenitrile gave in the reaction with naphthalene-1,4-dicarboxylic

SCHEME 27.19 Paternò-Büchi reaction on enamines.

SCHEME 27.22 The reaction of benzyl with a 2-aminopropenenitrile derivative.

acid in very low yields a product deriving from a Paternò-Büchi reaction [114]. The same result was obtained when benzil was used as substrate, while, when methyl phenylglyoxylate was used as carbonyl compound, the corresponding adduct was isolated in good yields [115].

Benzyl reacted with 2-aminopropenenitrile derivative to give the corresponding adduct in variable yields (Scheme 27.22) [116]. The reaction shows a good stereoselectivity. When unsymmetrical benzyl derivatives are used, both the isomers were obtained.

27.5 Reactions with Heterocyclic Compounds

27.5.1 Furan

Schenck reported that the irradiation of benzophenone in furan gave the corresponding adduct in 94% yield (Scheme 27.23) [117]. The structure was confirmed by Gagnaire et al. [118].

Two years later furan and 2-methylfuran were found to react with propanal and benzaldehyde [119–125]. The *exo* stereochemistry at C-6 on the dioxabicyclo[3.2.0]heptene skeleton has been

SCHEME 27.23 Paternò-Büchi reaction of furan with benzophenone.

assigned [126]. Good regioselectivity was observed using silyl and stannyl furan derivatives: the reaction in this case occurred on the less hindered side of the molecule [127]. 2-Silyloxyfuran gave a 1:1 mixture of regioisomeric products when it reacted with aliphatic carbonyl compounds or with benzaldehyde. On the contrary, the regioisomer obtained on the most hindered side of the molecule was obtained when benzophenone was used as a ketone. The same result was obtained using acetone in a reaction when a low concentration of furan was used. In all the cases, an *exo* selectivity was observed [128]. On the contrary, 2-furylmethanol and the corresponding silyl ether gave low regioselectivity [128,129].

The high *exo* stereoselectivity of the reaction has been extensively studied: the formation of the product occurs on a triplet 1,4-biradical, which must be converted into the singlet biradical to give the product. In order to explain the pronounced *exo* stereoselectivity, a secondary orbital effect can be postulated: an interaction between the rather flexible α -oxy radical center and the allyloxy ring localized radical in **53** likely plays a major role (Scheme 27.24) [130,131].

The regioisomeric biradical intermediates **A** and **B** resulting from the head-to-head and head-to-tail addition, respectively, have been examined (Figure 27.4) [83]. The biradical **A** is more stable than **B** by 16.5 kcal mol⁻¹. The biradical **A** exists as two conformers and we considered only that conformer able to give the ring closure.

The HSOMO is mainly localized on the benzaldehyde fragment of the biradical while the LSOMO is mainly localized on the furanoid part of the molecule. The coupling between the radical carbons in these two orbitals, considering that the atomic orbitals involved can superimpose themselves, can give only the *exo* isomer, in agreement with the experimental results (Figure 27.5).

SCHEME 27.24 The 1,4-biradical intermediate in the reaction between furan and benzaldehyde.

FIGURE 27.4 Possible biradical intermediates in the reaction of furan with benzaldehyde.

FIGURE 27.5 Ring closure reaction in the formation of the *exo* isomer of the adduct between furan and benzaldehyde.

When the reaction was carried out in benzene, dimers can be obtained [71,132–134]. Furan reacts with chloral to give unexpectedly the corresponding 2-furyl carbinols [135]. Furthermore, 2-cyanofuran did not react, while 2-furfural diacetate and furfural ethylene acetal showed low reactivity [135].

The cycloaddition reaction can be performed on esters. In this case, the adducts can be obtained in a few cases. In most of the examples, they underwent a cycloreversion reaction to give the ring opening products [136]. More recently, this result has been questioned and a 95:5 mixture of stereoisomeric adducts was identified as the product [131].

Coupling products can be obtained carrying out the reaction between an amide and furan: also in this case the cycloadduct cannot be isolated, but the subsequent decomposition products can be isolated [137]. Furan quenches the fluorescence of the substrate, while a small new emission at 500 nm appears, in agreement with a mechanism involving a reaction in the excited singlet state via the formation of an exciplex.

Schenck reported also the reaction of some aromatic carbonyl compounds (benzophenone, benzaldehyde) with benzofuran (Scheme 27.25); he showed that when high triplet energy compounds were used, dimers of benzofuran were obtained, while oxetanes were the products of the reaction when low triplet energy carbonyls were used [138]. As in the case of furan, he obtained only one product showing that the reaction has a high regioselectivity. Reinvestigation of the reaction of benzofuran with acetophenone or propiophenone showed that, also in this case, oxetanes were obtained [139].

The irradiation of **54** in the presence of benzaldehyde in benzene gave the corresponding adduct **55** in good yields (Scheme 27.26) [140]. It is interesting to note that the reaction allowed the formation of the *endo* isomer. The reaction between benzo[*b*]furan and benzaldehyde gave an adduct whose stereochemistry has not been described [138].

Oxetanes can be converted into the corresponding 3-furylcarbinol through reaction with TsOH [125]. The formation of a protonated oxetane is in agreement with the high negative entropy of the activation [141]. If the irradiation was performed in the presence of an acid, 3-furylcarbinol can be obtained in a one-step procedure in better yields [142]. This procedure has been used in the synthesis of perillaketone, a naturally occurring 3-substituted furan [142]. On the contrary, Lewis acids catalyzed a different behavior: the treatment with $\text{BF}_3 \cdot \text{Et}_2\text{O}$ gave only 3-substituted furan in THF and 89% of 2-substituted furan in acetonitrile [141].

The oxetane derivatives can be treated also with KMnO_4 and the resulting *cis* diol was treated with acetone in the presence of an acid. This procedure allows the synthesis of a carbohydrate derivative [143]. The same epimerization reaction occurs on the *trans* diol obtained through treatment of the oxetane with MCPBA [143]. The possible chemical modifications on the cycloadduct deriving from the reaction between an aldehyde and furan were extensively studied by Schreiber [144]. Hydrolytic ring opening, reductions, hetero Diels–Alder, the reaction with MCPBA, and hydroboration–oxidation were the

SCHEME 27.25 Paternò–Büchi reaction of benzofuran with benzophenone.

SCHEME 27.26 Paternò–Büchi reaction of a benzofuran derivative with benzaldehyde.

object of this work. The reaction with MCPBA was used by Schreiber and coworkers in the synthesis of asteltoxin [145,146], and in that of avenaciolide, an antifungal metabolite [147]. The reaction of tributylstannylfuran with butyl glyoxylate [127] was used in the synthesis of a ginkgolide B-kadsurenone hybrid of two inhibitors of a platelet-activating factor.

Furthermore, the cycloadduct obtained from the reaction between furan and an aldehyde can be treated with an excess of Schlosser's base (BuLi, *t*-BuOK) to give the corresponding anion, which can react with carbonyl compounds or alkyl halides [148].

A possible further application of the Paternò-Büchi reaction between carbonyl compounds and furan could be related to the use of the oxetane ring. The most important target in this field was oxetanocin (3), a nucleoside isolated from *Bacillus megaterium* NK 84-0218 showing anti-HIV activity. An approach to the synthesis of this compound has been reported [149]. Oxetanocin was obtained carrying out the reaction between 2-methylfuran and benzoyloxyacetaldehyde [150].

The reaction of glyoxylates with furan can be performed also using chiral glyoxylate. In particular, the use of *R*-(-)-menthol, 2-octanol, and 2,2-dimethyl-3-butanol as chiral auxiliaries gave the corresponding oxetanes in high yields. These compounds can be converted into the corresponding 3-substituted furans. The furans showed low enantiomeric excess (Scheme 27.27) [151]. On the basis of the experimental data the configuration of the oxetane was 1*R*, 5*S*, 6*S*.

The use of chiral phenylglyoxylate gave better results. The use of chiral alcohols gave diastereoisomeric excess in the range of 4%–80% (Scheme 27.28) [152–155].

The authors also observed an important variability of the diastereoisomeric excess in function of the temperature, with the presence of an inversion temperature. These results were explained assuming that the diastereoselection is produced on two levels: (1) the preferred formation of the diastereoisomeric 1,4-biradical intermediate **56** and (2) the preferred retrocleavage of the energetically unfavored diastereoisomeric intermediate **57** to the starting materials [156]. The diastereoisomeric excess in the high-temperature region ($T > T_{\text{inv}}$) is dominantly controlled by steric effects of the chiral auxiliaries, whereas in the low-temperature region ($T < T_{\text{inv}}$), the nature of the olefin has a dominating influence. When the reaction is carried out on 2-methylfuran, a 2:1 regioisomeric mixture was obtained with a very high diastereoisomeric excess [157].

SCHEME 27.27 The reaction of chiral-substituted glyoxylates with furan.

SCHEME 27.28 The reaction of chiral-substituted phenylglyoxylates with furan.

FIGURE 27.6 Radical intermediates in the reaction of chiral phenylglyoxylates with furan.

The best results in order to justify the observed stereoselectivity can be obtained considering the energy of the triplet biradical intermediates in the reaction of some phenylglyoxylate derivatives with furan [155]. Calculations on these biradical intermediates showed that **58** (the precursor of the observed product) was more stable than **59** by $0.73 \text{ kcal mol}^{-1}$ (Figure 27.6).

To improve diastereoselectivity, the reaction was carried out in an organized medium. In another study the chiral phenylglyoxylate esters were used in the presence of different zeolites [158]. NaY was the best solid support for this reaction. The origin of this behavior can be explained considering the possible effect of the confinement on the reaction. In the Paternò–Büchi reaction on furan derivatives the biradical intermediate **60** can assume two possible conformations [26,83]. One of these has the radical carbons in almost *anti* conformation, while the other one is almost a *syn* conformation (Scheme 27.29).

The *syn* conformation is in a steric situation where the following cyclization, after the intersystem crossing from the triplet to the singlet state, is a favored process. In the *anti* conformation the most favored process is the retrocleavage to the starting material. The *syn* conformations take up a smaller volume than the *anti* one. The preferential formation of a stereoisomer in the reaction within a zeolite can be explained: the *SS-syn* conformer is obtained preferentially, while the *RS* conformer is obtained preferentially in *anti* conformation. The latter conformer has to rotate along the C–O bond to give one able to cyclize. Zeolites can act as agents able to reduce the conformational mobility of the intermediates, inhibiting the rotation of this conformer and, then, favoring the formation of the product deriving from the *SS* biradical intermediate.

The reaction of furan with acyl cyanides yields the corresponding oxetanes but both diastereoisomeric *endo*- and *exo*-oxetanes are formed. When chiral acyl cyanides are used, low asymmetric induction is observed [159]. Furan reacts also with chiral ketones. In this case, an α -cleavage reaction before the $2 + 2$ cycloaddition modifies the expected products (Scheme 27.30). When (–)-menthone was used as a substrate, a chiral product was obtained as 2:1 diastereoisomeric mixture where the most abundant product has 1*R*, 3*R* configuration [160]. When the reaction was performed on the ketonic group of a protected carbohydrate, a complex reaction mixture was obtained [160,161].

Attempts to obtain stereoselective Paternò–Büchi reactions were performed carrying out the reaction between 3,4-dimethylfuran and *R*-isopropylidene glyceraldehyde. The coupling products were obtained with an overall yield of 35% as a 1.2:1 mixture of diastereoisomers. Furthermore, the compound **61** was obtained with 54% ee (Scheme 27.31) [162,163].

This behavior suggests the operation of a mechanism that is insensitive to the substitution pattern of chiral aldehydes. Reaction between an excited aldehyde (singlet or triplet state) and furan proceeds with initial carbon–oxygen bond formation to produce either of the two biradical species. The stereocenter adjacent to the carbonyl is now in a 1,4-relationship to the newly formed stereocenter at the acetal carbon and is expected to exert little influence as a stereocontrol device [162]. The extensive racemization

SCHEME 27.29 Possible conformations in the Paternò–Büchi reaction of benzophenone with furan.

SCHEME 27.30 Paternò-Büchi reaction between dialkyl ketones and furan.

SCHEME 27.31 Paternò-Büchi reaction of *R*-isopropylidene glyceraldehyde with furan.

observed probably reflects the photolability of the aldehydes toward racemization under the conditions of the reaction [163]. Nevertheless, compound **61** can be used in a chiral synthesis of the bicyclic part of asteltoxin confirming the assigned absolute configuration [163]. If the chiral center is near the reaction site the diastereoselectivity increases. Benzoin reacted with furan to give the corresponding adduct in acceptable yield (56%) and *de* > 98% (Scheme 27.32) [164].

The observed stereoselectivity was explained considering the relative stability of the biradical intermediates. When chiral ketones were used as substrates the Norrish type II reaction is the only observed reaction. In order to avoid Norrish type II reaction a substrate without γ -hydrogen was used [165].

In 1990 Griesbeck found that the reaction of benzaldehyde with homoallylic alcohols did not show diastereoselectivity [77]. Ten years later, Adam showed that allylic alcohols reacted with benzophenone to give the corresponding adducts with high regio- and diastereoselectivity (Scheme 27.33) [166–169].

The diastereoselectivity dropped drastically in presence of protic methanol and totally disappeared for the corresponding silyl ethers. These data are in agreement with the presence of a hydroxyl directing

SCHEME 27.32 Paternò-Büchi reaction of benzoin with furan.

SCHEME 27.33 Paternò-Büchi reaction of allylic alcohols with benzophenone.

effect in the Paternò-Büchi reaction. *Threo* stereoisomer can be favored through the formation of a hydrogen bond between triplet excited benzophenone and the substrate in the exciplex, while the formation of the *erythro* stereoisomer would be less favored due to allylic strain.

The formation of a hydrogen bond to direct the Paternò-Büchi reaction has been considered by other researchers. Diastereoselective cycloaddition has been obtained using chiral enamide [170,171], or in the reaction of allylic alcohols with naphthalene rings [172]. When unsymmetrical carbonyl partners such as acetophenone or benzaldehyde were used, high diastereoselectivity was observed to give the corresponding *cis* isomer. The regioselectivity was high with acetophenone but lower with benzaldehyde [167].

Cis diastereoselectivity can be explained by using the Griesbeck rule on the possible triplet biradicals formed in the reaction. Steric interactions are minimized when the biradical assumes the optimal conformation and this conformation accounts for the formation of the observed stereoisomer [169].

When chiral allylic alcohols were used as substrates in the reaction *cis* diastereoisomers were formed. Furthermore, also in this case, a pronounced *threo* diastereoselectivity was observed, in agreement with a less pronounced hydroxy directing effect when acetophenone and benzaldehyde were used [167,169]. Chiral allyl ether gave the corresponding adduct with high diastereoselectivity [106].

The reaction of 2,3-dihydrofuran-3-ol derivatives (a particular type of allylic alcohol) with benzophenone gave the corresponding adducts showing that in methanol a *trans* relationship between the oxetane ring and the hydroxyl group was obtained, while, in benzene the *cis* isomer prevailed. The Eyring plot showed that the *trans* isomer increased with a not linear behavior decreasing the temperature [173].

The reaction of allylic alcohols with carbonyl compounds was tested also on a particular type of allylic alcohol such as 2-furylmethanol derivatives. The presence of large substituents on the carbon bearing the alcoholic function allows a high regioselectivity (Scheme 27.34) [174].

When 5-methyl-2-furyl derivatives were used as substrates, a different regioselectivity was observed. Compound **62** gave a 1:1 mixture of regioisomers, when irradiated in the presence of benzophenone, and a single regioisomer in the presence of benzaldehyde (Scheme 27.35) [175]. In agreement with the results obtained with 2-furyl derivatives, the products deriving from the attack on the side bearing the alcoholic function were obtained as a single diastereoisomer, while those deriving from the attack on the side bearing the methyl group were obtained as a mixture of diastereoisomers.

SCHEME 27.34 Paternò-Büchi reaction on 2-furylmethanol derivatives.

SCHEME 27.35 Paternò-Büchi reaction on 5-methyl-2-furylmethanol derivatives.

The reaction of 2-furylmethanol derivatives with aliphatic aldehydes and ketones gave the corresponding adducts with high regioselectivity (on the most hindered side of the substrate) but no diastereoselectivity [176]. The regioselectivity of the reaction was explained on the basis of the relative stability of the biradical intermediates. Theoretical study (density functional theory [DFT]) showed that the biradical obtained on the most hindered side of the molecule was more stable than the other one [175].

The observed diastereoselectivity in the reaction with aromatic carbonyl compounds clearly shows that it increases in relation to the nature of the substituents on the carbon bearing the alcoholic function as described by Adam. However, while Adam considers the allylic strain with a methyl group as the driving force for the diastereoselectivity, in this case, the methyl group is not present.

In order to have more data to explain the observed stereoselectivity, the photochemical behavior of tertiary 2-furylcarbinols was studied [177]. The photochemical reaction of 1-methyl-1-phenyl-1-(2-furyl)methanol with benzaldehyde gave a mixture of two regioisomeric product. The regioisomer on the most hindered side of the molecule was obtained in low yield but it showed a complete diastereoisomeric control. On the contrary, the main product was a mixture of four diastereoisomeric products (Scheme 27.36). The reaction of the same compound with benzophenone gave only the product

SCHEME 27.36 Paternò-Büchi reaction on tertiary 2-furylcarbinols.

FIGURE 27.7 Possible conformations of the biradical intermediate from the reaction of 1-methyl-1-phenyl-1-(2-furyl) methanol with benzaldehyde.

deriving from the attack on the most hindered side of molecule. This compound was obtained with 48% diastereoisomeric excess.

The regioselectivity was explained, as described earlier, considering the relative stability of the biradical intermediates. In this case, in the reaction of the 1-methyl-1-phenyl-1-(2-furyl)methanol with benzaldehyde the biradical obtained on the less hindered side of the substrate was more stable than the other one by $18.03 \text{ kJ mol}^{-1}$. The same behavior was not observed using cyclic 2-furyl methanol derivatives [178].

On the basis of these results, an explanation of the stereochemical behavior was attempted [177]. 1-methyl-1-phenyl-1-(2-furyl)methanol showed three conformations. All three conformers were in the range of 1.97 kJ mol^{-1} and they did not show a preference. The directing effect exerted by the hydroxyl group is due to the formation of a hydrogen bond between the hydroxyl group and the oxygen of the excited carbonyl compound, or it is due to the formation of a complex. This type of interaction could favor the formation of a preferential conformation in the biradical intermediate where the hydroxyl group and the oxygen of the carbonyl compound are near. These conformations could have different energies for different diastereoisomeric biradicals, giving an explanation of the observed behavior. The aforementioned hypothesis requires that the biradical intermediates have a very short life enabling them to equilibrate to the most stable one. In the case of 1-methyl-1-phenyl-1-(2-furyl)methanol, if the hydroxyl group drives the attack of the oxygen of the carbonyl group, the conformations of the biradical intermediate represented in Figure 27.7 were obtained. **B** and **D** are the preferential conformation: calculations on these conformations showed that there is a difference of $13.26 \text{ kJ mol}^{-1}$ between the energies of these two conformations. This difference can account for the observed complete diastereoselectivity of the reaction. In the reaction of the same substrate with benzophenone the corresponding conformers **B** and **D** show a energy difference of 7.79 kJ mol^{-1} ; this difference is in agreement with the observed diastereoselectivity.

The same approach can be used to justify the stereochemical behavior of the reaction of allylic alcohols with benzophenone [179]. The irradiation of (*R*)-**63** in the presence of benzophenone gave (1*S*,5*S*,1'*R*)-**64** (Scheme 27.37) [180]. The stereochemical behavior was explained considering the same approach described earlier.

SCHEME 27.37 Paternò-Büchi reaction on 3-furylmethanol derivatives.

27.5.2 Other Pentaatomic Heterocycles

The reactivity of pentaatomic aromatic heterocycles different from furan toward carbonyl compounds to give the corresponding oxetanes has been the object of other review articles [181]. These compounds show lower reactivity than furan. The reason of this behavior is not clear. It could be related to the different aromaticity of these compounds in comparison with that of furan, or could be due to the quenching properties of the heterocycles.

Thiophene does not react with benzophenone. It reacts only when irradiated in the presence of BF_3 [182]. In this reaction, BF_3 is able to catalyze the ring opening of the oxetane. On the contrary, dimethylthiophenes react with benzophenone to give the corresponding cycloadduct with high regioselectivity [122,183–185]. On the contrary, 2,3-dimethyl- and 2,3,5-trimethylthiophene do not react.

Pyrrole, such as thiophene, does not react with benzophenone to give the corresponding oxetane. However, pyrrole reacts with aliphatic aldehydes and ketones to the corresponding 3-pyrrol carbinols [186]. Pyrrole can give the corresponding oxetane when irradiated in the presence of benzophenone only when an electron-attracting group such as benzoyl is bounded to the nitrogen atom [187,188].

Selenophene does not react with benzophenone [122]. On the contrary, 2-methylselenophene gives the corresponding cycloadduct. Also in this case the reaction occurs on the most hindered side of the molecule [189].

Imidazole, *N*-methylimidazole, and 1,2-dimethylimidazole react with aliphatic aldehydes and ketones to give the corresponding 4-imidazolyl carbinols in good yields [186,190]. 1,2-Dimethylimidazole reacts with benzophenone giving in low yield a reaction on the methyl in 2 position [191,192]. Some other imidazole derivatives showed the same behavior [191–193].

2,4-Dimethylthiazole gives the corresponding oxetane when irradiated in the presence of benzophenone [192].

Aliphatic and aromatic carbonyl compounds react with oxazole derivatives with good to high *exo* diastereoselectivity, but low facial stereoselectivity. This reaction can be used in the synthesis of *erythro*- α -amino β -hydroxy carboxylic acid derivatives [194–198].

Indole does not react with benzophenone under irradiation condition. On the contrary, a benzoyl derivative reacts with it, giving the corresponding oxetane [199]. The same reaction has been described on *N*-acetyl derivative of 7-azaindole. Although the reaction represents a method able to obtain a new class of compound, the low yields of the product (4%) prevent a synthetic use of this reaction [200].

The results reported earlier represent all the available data on the Paternò-Büchi reaction on pentaatomic heterocycles different from furan. We can see that there are very few data: in particular, (1) most of the unsubstituted compounds tested did not react and (2) only few substituted derivatives showed a significative reactivity toward excited carbonyl compounds.

This behavior can be due to different reasons. First, the different aromaticity of the compounds could play an important role in order to define the reactivity of the compounds. Furan is the lowest aromatic pentaatomic heterocyclic compound known, while the other compounds show higher aromaticity. However, this type of explanation cannot justify why thiophene does not react while simple dimethylthienyl derivatives react and why some dimethylthienyl derivatives react while some others do not show any reactivity.

Stern–Volmer analysis of the quenching of benzophenone photoreduction showed that *N*-substituted pyrroles and selenophenes need an electron transfer mechanism [201].

27.5.3 Pyrimidines

The (6-4) photoproduct is an adduct of two pyrimidines that occupy adjacent sites on the same DNA strand. It is the second major lesion induced in DNA by UV radiation. Although statistically four times less frequent than CPD lesion, (6-4) photoproducts are believed to be severely mutagenic. Its formation is believed to occur via an initial Paternò-Büchi type cycloaddition to form an oxetane intermediate. Subsequent C4–O bond cleavage gave the observed (6-4) photoproducts. This is one of the major mutagenic classes of DNA photoproduct and is involved in the etiology of skin cancer. The oxetane **65** was prepared in a triplet reaction and both electron donor and acceptor substituents were found to be able to photosensitize the splitting reaction (Scheme 27.38) [202–205]. Only one regioisomer (**65**) was observed. The other regioisomer **66** was rarely observed [206].

The regiochemistry of the reaction depends on the temperature. At -38°C the regioisomer **65** dominates (61:39). On the other hand, at 70°C the regioisomeric behavior of the reaction is inverted [207,208]. A nonlinear Eyring plot was obtained showing a change of the selectivity-determining step. This behavior can be explained assuming two different cases: the situation where the conformational changes of the triplet intermediates are slower than ISC at low temperature and the case where the conformational changes exceed the ISC process [207]. When the conformational interchange is faster than the ISC process, the population of high potential energy conformations decreases, while the population of a lower potential energy conformer increases. The substituents on benzophenone modify the regiochemistry of the reaction: When *p*-methoxybenzophenone is used on 1,3-dimethyluracil, the isomer **65** is obtained (**65/66** > 95:5), while, using *p*-cyanobenzophenone, a 32:68 **65/66** ratio was observed [208,209]. The photochemical efficiency correlates with the energy gap between SOMO of benzophenone derivatives and the HOMO of the base. A small energy gap implies a strong interaction, and then a higher efficiency of the reaction. Recently, a theoretical approach to this reaction has been performed [210]. The authors considered the biradical intermediates **67** and **68** (Figure 27.8). They found that **68** is more stable than **67**, and that the formation of **67** is faster than **68**. Then, **66** can be considered as a thermodynamic product, while **65** a kinetic one.

A weak solvent effect was observed on the regioselectivity of the reaction [211]. The oxetane was obtained also in the reaction between benzophenone and benzophenone-derived drugs and thymidine [206,212]. An enantioselectivity factor for triplet deactivation was found using enantiopure ketoprofen. The enantioselective quenching of the chiral ketoprofen triplet state by thymidine can be associated with the formation of C–O bond, the first step of oxetane formation [81]. An intramolecular reaction

SCHEME 27.38 Paternò-Büchi reaction of a pyrimidine derivative.

FIGURE 27.8 Biradical intermediate in the reaction of dimethyluracil.

SCHEME 27.39 Intramolecular photochemical reaction between two pyrimidine units.

between thymidine esterified by ketoprofen has been described [213]. The irradiation of **69** gave **71** deriving from the (6–4) photoadduct **70** (Scheme 27.39) [214].

A reaction between 5-fluoro-1,3-dimethyluracil with 1,5-dimethoxynaphthalene has been reported [215]. The reaction gave product where an aromatic ring of naphthalene is broken. The presence of the intermediate cycloadduct has been proposed.

27.6 Intramolecular Reactions

2,7,9-Trimethylenetricyclo[4.3.0.0^{3,8}]nonane **72** can be obtained in a synthetic procedure involving an intramolecular Paternò-Büchi reaction of **73** to give **74** (Scheme 27.40) [216].

The same synthetic scheme was used in the synthesis of 2,7,9-trimethylenetricyclo[4.3.0.0^{3,8}]non-4-ene [217]. Some stelladiones such as tricyclo[3.3.0.0^{3,7}]octane-2,4-dione **75** or tricyclo[3.3.0.0^{3,7}]octane-2,6-dione **76**, were obtained using the same synthetic strategy (Scheme 27.40) [218]. This type of intramolecular reaction was used also in the synthesis of diquinanes and triquinanes (Scheme 27.41) [219–221].

The synthesis of 1,13-herbertenediol **77** was performed using the same approach (Scheme 27.42) [222]. Intramolecular stereoselective Paternò-Büchi reactions were observed also in the reaction of some derivatives of *R*-(+)-sclareolide [223]. A synthesis of the scaffold of merrilactone A involved also an intramolecular 2 + 2 cycloaddition to give the adduct **78** (Scheme 27.42) [224].

SCHEME 27.40 Paternò-Büchi reaction in the synthesis of tricyclononane scaffolds.

SCHEME 27.41 Synthesis of diquinanes and triquinanes.

SCHEME 27.42 Synthesis of 1,13-herbertenediol (**77**) and of merrilactone scaffold.

SCHEME 27.43 Paternò-Büchi reaction on allylcyclopentanone derivatives.

On the other hand, an attempt to obtain tromboxane analogs using an intramolecular reaction of a carbonyl group with an enol ether, failed [225]. An intramolecular reaction on allyl cyclopentanone derivatives has been reported [44,226,227]. In this case both *straight* **80** and *crossed* **81** oxetanes can be obtained (Scheme 27.43). Using 2-allylcyclopentanone nearly equal amounts of these isomers were obtained: the use of the more rigid starting material **79** allowed the preferential formation the *straight* isomer.

An intramolecular cycloaddition reaction was found in the reaction of **82** to give **83** (Scheme 27.44) [228].

The reaction of **84** gave in quantitative yield the oxetane **85** that can be converted into **86** via fluoride desilylation (Scheme 27.45) [229].

SCHEME 27.47 Stereoselective intramolecular Paternò-Büchi reaction on an amide derivative.

SCHEME 27.48 Norrish-type I and Paternò-Büchi reaction on the ketone **91**.

Some years ago, Scharf and coworkers studied the Paternò-Büchi reaction between electron-rich alkenes and chiral phenyl glyoxylates [156,230]. Neckers studied the reaction of ethyl phenylglyoxylates with several alkenes showing that it gave the cycloaddition reaction only when electron-rich alkenes were used. Monosubstituted alkenes gave Norrish type II reaction and the same behavior was observed reducing the electron richness of the alkenes [231]. Methyl 2-thienylglyoxylate showed a transient absorption at 390 nm and a broad band around 600 nm assigned to the triplet state and this compound reacts with 2,3-dimethyl-2-butene to give the corresponding adduct [232]. When alkenyl phenylglyoxylates were used as substrates, Norrish type II is the main reaction in most of the cases, with the exception, for example, of compound **87** able to give the adduct **88** (Scheme 27.46) [233,234].

N-Isopropyl-*N*-tigloylbenzoylformamides gave an intramolecular cycloaddition reaction in high yields (50%–99%) to give the *syn* adduct (*syn/anti* = 2.1) [235,236]. The compound **89**, irradiated in solid state showed a different behavior: the crystals of **89** are in a chiral group, so **89** gave **90** with a *syn/anti* = 6.7 and *syn-90* was obtained with a high ee value (>99%) (Scheme 27.47) [236].

When the ketone **91** was irradiated in the solid state, a Norrish type I reaction occurred, giving an alkene and a carbonyl compounds, able to give the corresponding adduct **92** (Scheme 27.48). The reaction occurs with high stereoselectivity, and, when performed on a chiral salt gave the product with ee in the range 42%–52% [53].

28.1 Introduction

Quinones are ubiquitous in biological systems and cofactors in the photosynthetic reaction centers where the initial products are radical ion pairs. The photochemistry of quinones has been intensively investigated and reviewed earlier (Bruce 1974). Thereafter, advances and new applications were presented (Maruyama and Osuka 1988). The scope of the quinone photochemistry covers a broad range from being a key molecule in a computational model of photocatalytic water splitting (Sobolewski and Domcke 2008) to the material on bioinspired electron transfer (ET) systems (Fukuzumi 2006) as well as the natural and artificial photosynthetic energy conversion (Barber 2009). The application of quinone cycloaddition is widespread, extending from the beginning of photochemistry to modern applications and has been updated in several contributions (Creed 1994, Maruyama and Kubo 1994, Gilbert 2004, Oelgemöller and Mattay 2004). Attention has been focused on the production of fine chemicals with quinones and sunlight (Oelgemöller et al. 2007). A further review deals with the role of quinones in toxicology (Bolton et al. 2000). The literature concerning quinones in both synthetic photochemistry and photosynthetic reaction centers is numerous and only a few selected papers could be cited here.

This chapter aims at a deeper insight into the quinone photochemistry in organic solvents. Another approach refers to the specific role of water in these photoprocesses. An adequate description of the field would greatly exceed the allocated space. This chapter is therefore limited to a presentation of the 2009 state-of-the-art mechanistic aspects; it focuses on quinones mainly from a reactivity point of view and does not deal too much with photosynthetic topics. Nevertheless, some earlier studies are highlighted and the references may allow the reader to find an entry into the wider literature. A major goal is a systematic presentation and better understanding of the fundamental framework of reactions. In order to gain an insight into the details of the molecular structure versus function relationship, the effects of specific additives on the intermediates and reactivities of a series of 1,4-benzoquinones (BQ),

1,4-naphthoquinones (NQ), and 9,10-anthraquinones (AQ) are presented in a compact form. The presentation refers to *p*-quinones in solvents at room temperature, whereas *o*-quinones and low temperatures are mostly omitted or indicated where considered.

28.2 Photoreduction

The photoreduction of BQ, NQ, AQ, and their derivatives is rather efficient and follows a common mechanism. The quantum yields of formation of dihydroquinones (QH₂) in the presence of a donor (DH₂) are up to unity. In particular, anthraquinol, the corresponding QH₂, is formed for AQ in mixtures of benzene and 2-propanol with $\Phi = 0.9$ –1 (Wilkinson 1962, Schulte-Frohlinde and von Sonntag 1965). Most organic solvents react with excited quinones and these processes can be analyzed clearer using an inert solvent and an alcohol or amine. 2-Propanol and triethylamine (TEA) were chosen here as two model donors owing to a high reactivity and virtually no absorption at 254–313 nm for the latter. Some quantum yields are compiled in Table 28.1. For comparison, $\Phi^{\text{TEA}} = 0.4$ for both BQ and duroquinone (Me₄BQ), but 0.05 for ubiquinone-0: 2,3(OMe)₂MeBQ (UQ₀) (Görner 2003a). Generally, the quantum yield of decomposition in the absence of a donor is small or moderate, for example, 0.002–0.05 for BQ, NQ, or AQ (Görner 2003b). Examples of the photoinduced spectral changes are shown in Figure 28.1 for BQ and Me₄BQ. A minimum of reaction steps is shown in Scheme 28.1.

SCHEME 28.1 Photoreduction in the presence of donors via H-abstraction and ET.

Excitation of the ground state leads to the first excited singlet state (1Q), step (1), which is characterized by its electronic energy and by different vibrational states. Decay of 1Q leads to the lowest triplet state (3Q), step (2). The molecule also can fluoresce or revert radiationlessly to Q through internal conversion. Irradiation in the presence of DH_2 -type additives then generates long-lived semiquinone radicals, reaction (3), and finally a relatively stable dihydroquinone, step (5). In competition, triplet quenching by oxygen (4) occurs, and some consequences are discussed in Chapter 9. The radical anion ($Q^{\bullet-}$) and the conjugated semiquinone radical ($^{\bullet}QH$) are rather unique (cf. Rosokha et al. 2009) and the earlier literature of short-lived radicals has been reviewed (Khudyakov and Kuzmin 1975, Das and Venkataraman 2005). For all three types, BQs, NQs, or AQs, optimized conditions can be chosen, where Φ^{Donor} is close to unity. This likewise implies a quantum yield of intersystem crossing (Φ_{isc}) of close to unity. Two semiquinone radicals are formed by one photon, whereby one radical is due to H-atom transfer from the alcohol and one from the donor radical. Alternatively, ET from an amine to 3Q takes place; for details see Chapters 4, 5, and 7. Nevertheless, several changes, for example, substitution with electron-donating groups, can lower the reduction significantly, for example, for $(OMe)_2BQ$ where $\Phi^{2P} = 0.01$ and $\Phi^{\text{TEA}} = 0.05$ (Görner 2003a).

28.3 Excited Singlet State and Ground State Reactions

The absorption spectrum of BQ has a maximum at 240 nm (Figure 28.1a) with a molar absorption coefficient of $2 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ and extends to the visible with $\epsilon_{440} = 200 \text{ M}^{-1} \text{ cm}^{-1}$. Those of BQ derivatives are redshifted (see Figure 28.1b) for Me_4BQ . For NQ the values are $\epsilon_{250} = 2 \times 10^4$ and $\epsilon_{330} = 3 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$; for AQ $\epsilon_{250} = 5 \times 10^4$ and $\epsilon_{400} = 90 \text{ M}^{-1} \text{ cm}^{-1}$. Substitution of AQ has relatively large effects and various AQs serve as dyestuffs (McKellar 1971). Concerning ground state interactions, a few papers should briefly be mentioned. In some cases, for example, xanthene dyes and quinones, complexation has been reported, the association constants are $20\text{--}1500 \text{ M}^{-1}$ (Gutiérrez and García 1998). Chlorin pigments show hypsochromism, when complexed with BQs (Mennenga et al. 2006). A thermal reduction of quinones by OH^- or MeO^- can take place (Fukuzumi and Yorisue 1991). Another thermal quinone reduction is known (Pandey 1982, Isaacs and van Eldik 1997) in the presence of ascorbic acid (vitamin C: AscH).

The excited singlet state of most quinones is extremely short lived. Population of the lowest triplet state of parent BQ occurs within 20 ps, as concluded from hydrogen abstraction in a time-resolved Raman scattering study (Rossetti and Brus 1986). This is in excellent agreement with data for BQ in acetonitrile (Yuasa et al. 2004). The fast ET from a singlet excited pigment to a quinone is the subject of various studies (see Chapter 11). For BQs and NQs, the 3Q state (rather than 1Q) is the first spectroscopically and kinetically accessible species. One exception is constituted by hydroxyAQs (Diaz 1990), where the ISC step is longer than a few picoseconds. HydroxyAQs therefore exhibit fluorescence, but the quantum yields (Φ_f) are generally smaller than 0.01 (Table 28.2). AlkylaminoAQs belong to another class of quinones showing fluorescence. AminoAQs have a fluorescence maximum in the 500–600 nm range, small or moderate Φ_f and a fluorescence lifetime (τ_f) of 0.2–5 ns (Müller et al. 2006); some properties are compiled in Table 28.3. For purpurin in acetonitrile $\Phi_f = 0.08$ and $\tau_f = 2 \text{ ns}$ (Del Giacco et al. 2003). The fluorescence of quinizarin is quenched by a series of amines (Kumbhakar et al. 2004). Intramolecular charge transfer (CT) can occur through hydrogen bonding. For 2-aminoAQ the major deactivation

occurs radiationlessly through hydrogen bonding, that is, via intramolecular CT (Morimoto et al. 2001). A hard-soft anionic character in the excited singlet state has been suggested (Umadevi et al. 2008). Nevertheless, most quinone reactions start from the ³*Q state.

28.4 Triplet State Reactions of BQs and NQs

The T-T absorption spectra of BQ or NQ have a major band at 300–320 nm and a minor one at 400–500 nm. Φ_{isc} of various quinones is high (0.5–1), based on photoacoustic calorimetry (Sarpa and Arnaut 2000). This, however, does not hold for BQs with electron-donating groups including ubiquinones (Land et al. 1971). For UQ₃₀, Φ_{isc} = 0.04–0.09 (Bensasson et al. 1972, Amouyal et al. 1974). For comparison, Φ_{isc} = 0.15 for 2,5-(OMe)₂BQ. The triplet energy (E_T) of BQ is 220 kJ mol⁻¹ and the one-electron reduction potential (vs. SCE) E^0 = -0.52 and 0.08 V in acetonitrile and water, respectively. Examples for significant effects of structure on E_T and E^0 are compiled in Table 28.4, for example, E^0 = 0 for Cl₄BQ in acetonitrile.

^a In acetonitrile (Goez and Frisch 1995).^b Vs. SCE.^c In water (Roginsky et al. 1999).

The triplet lifetime of quinones (τ_T) in oxygen-free nonaqueous solution is up to the millisecond time range. However, for many BQs or NQs at room temperature, τ_T is as short as a few microseconds. In a typical experiment, when time-resolved UV-vis spectroscopy with 248 or 308 nm pulses is applied, $\tau_T = 5\text{--}10\ \mu\text{s}$, for example, for BQ in acetonitrile? (Serpa and Arnaut 2000, Görner 2006a). The triplet state of quinones is quenched by oxygen, the rate constant ($k_4^{O_2}$) of quenching is $(0.3\text{--}3) \times 10^9\ \text{M}^{-1}\ \text{s}^{-1}$, and some values are listed in Table 28.5. For UQ₃₀ in benzene $k_4^{O_2} = 1.5 \times 10^9\ \text{M}^{-1}\ \text{s}^{-1}$ (Bensasson et al. 1972). The major step of triplet quenching by oxygen is formation of singlet molecular oxygen. The quantum yield (Φ_Δ) of its formation is relatively large (see Chapter 9). Φ_Δ can be considered as a minimum of Φ_{isc} . Note that the triplet can undergo a specific quenching process by ground state quinone, the so called self-quenching reaction (see Chapter 7). This shortens τ_T markedly and can lead to radicals as intermediates and eventually to additional photoproducts. Thus, one can expect a limiting τ_T and no secondary products only at a low enough quinone concentration.

Secondary intermediates can be produced by reaction of the triplet with the solvent or other donors. The rate constant of triplet quenching by TEA and 2-propanol, reaction (3), depends essentially on the conditions, for example, the one-electron potentials in the case of ET. For BQ in acetonitrile $k^{2P} = 9 \times 10^7\ \text{M}^{-1}\ \text{s}^{-1}$ and $k^{TEA} = 1 \times 10^{10}\ \text{M}^{-1}\ \text{s}^{-1}$ and for other quinones the rate constants are smaller. Some effects of substitution on k^{Donor} can be seen in Table 28.5. For 2-OMeBQ in acetonitrile $k^{EtOH} = 1 \times 10^7\ \text{M}^{-1}\ \text{s}^{-1}$ and for Me₄BQ k^{EtOH} is as low as $(2\text{--}3) \times 10^4\ \text{M}^{-1}\ \text{s}^{-1}$ (Scheerer and Grätzel 1977), that is, methoxyBQs and

Verhoeven 1997). Photocyclization of 2,5-Cl₂-3,6-bis(dialkylamino)BQ is wavelength dependent (Shi et al. 2007). Depending on the conditions, for example, solvent polarity, the mechanism can be directed to different product distributions. The singlet ion pair of chloranil (Cl₄BQ) and aromatic donors is formed within 5 ps (Hubig et al. 1997). Quinones function as sensitizers for preparative photolysis and especially Cl₄BQ has been frequently employed in this role (Gschwind and Haselbach 1979, Bergmark and Jones 1997, Jones et al. 1997, Baciocchi et al. 1998, Bosch et al. 1998, Hubig and Kochi 1999, Del Giacco et al. 2001, Fukuzumi et al. 2001, Latour et al. 2005, Krongauz and Kim 2006, Murakami et al. 2008). The formation of enrofloxacin, levofloxacin, and ofloxacin with Cl₄BQ is rapid and sensitive (Ulu 2009). Dimers result from semiquinone radicals, for example, for methoxyBQs (Marquardt et al. 1992, Béarnais-Barbry et al. 2001). Some related topics with BQs have been discussed (Kuzmin et al. 1979, Levin et al. 1996, Goetz and Eckert 2006). The semiquinone radical can also be formed in biomimetic materials based on SiO₂ and indole (Christoforidis et al. 2008).

The triplet state properties of NQs in organic solvents have been studied by several groups (Gan and Whitten 1993, Amada et al. 1996, Mac and Wirz 2002). The triplet state of parent NQ is short lived and the T-T absorption is overlapped with that of the long-lived semiquinone radical. The addition of substituents lowers the intermolecular reactivity for most of the NQ derivatives, but does not drastically change the overall behavior in nonaqueous solution. The photoproduct of 2,3-Cl₂NQ in the presence of furan is 2-Cl-3-furanylNQ and Φ is up to 0.12 (Yamaji et al. 1999). The photoreaction between Cl₂NQ and *N,N'*-diphenylthiourea involves an electron donor acceptor adduct as intermediate (Datta and Mukherjee 2004). Formation of singlet molecular oxygen is efficient for NQs (see Φ_{Δ} in Table 28.6). Φ_{Δ} = 0.6–0.7 for juglone and plumbagin in acetonitrile. For lapachol: 2-hydroxy-3-(3-methyl-2-butene-1-yl)NQ, Chart 28.1, however, where Φ_{Δ} in CCl₄ is nearly zero, an efficient singlet reaction takes place; this is similar for vitamin K₁ and plumbagin (Chapter 10). The reactivity and photosensitizing properties of the triplet state of α - and β -lapachone have been characterized (Ci et al. 1989, Netto-Ferreira et al. 2008, 2009). ET from TEA to triplet NQ within 1 μ s and the radical decay within 0.2 ms is shown in Figure 28.3a. For MeNQ in acetonitrile $k^{\text{TEA}} = 2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ (Swartz et al. 2008). The triplet states of mono- and dimethylnqs were studied at low temperatures (Shimokage et al. 1997), and the phosphorescence lifetime of 2-OMeNQ in (m) ethanol at 77 K is 4 ms (Aaron and Winefordner 1972). Similar lifetimes have been found for Cl₂NQ

and vitamin K₁ and somewhat shorter ones for NQ and BrNQ (Amada et al. 1995). The Paterno-Büchi reaction between NQ and anetholes in polar solvents involves ET (Eckert and Goetz 1994). The photoacylation of 2-R-NQs gives access to biologically active NQs (Friedrichs et al. 2008).

28.5 Photoreactions of AQs

The triplet state properties and subsequent radical reactions of AQs are in principle the same as for BQs and NQs. ET and H-transfer to triplet AQ were studied by CIDEP and flash photolysis (Yoshihara et al. 2000, 2001). An example of ET from TEA is shown in Figure 28.3b for Me₂AQ, where, in contrast to AQ, the T-T and radical absorption spectra are well-enough separated (Görner 2003c). AQs provide a wide application potential due to the large variety in substitution pattern (Hamanoue et al. 1992). One class contains hydroxy groups, another alkylamino, and a third nitro groups. Marked effects of substitution on Φ can be seen from the data compiled in Tables 28.2 and 28.3. For alizarin, a naturally occurring hydroxyAQ, $\Phi_{\Delta} = 0.03$. For 1,5-(OH)₂AQ in acetonitrile $\Phi_{\Delta} < 0.01$, whereas $\Phi_{\Delta} = 0.5$ for 1,8-(OH)₂-4,5-(MeO)₂AQ in benzene (Davies et al. 1972a). Aloe emodin, due to a substantial Φ_{isc} , exhibits phototoxicity (Vath et al. 2002). The ratio $S_{\Delta} = \Phi_{\Delta}/\Phi_{isc}$ is close to 1 for AQ and depends significantly on substitution. Introduction of amino groups causes CT effects, which lowers Φ_{isc} significantly (Table 28.2); a certain part of the excitation energy dissipates as internal conversion.

For 1,4-diazabicyclo[2.2.2]octane (DABCO) as specific amine, virtually no QH₂ product can be observed, whereas the k^{DABCO} values are high and similar to those with TEA. The reason is efficient electron back transfer, thereby restoring both the amine and the quinone. For ClAQ $\Phi^{TEA} = 0.9$ (Hamanoue et al. 1985). For 1,8-(OH)₂AQ in acetonitrile $k^{Anilin} = (2-19) \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for triplet quenching by anilines (Pan et al. 2007). Triplet quenching reactions by dimethyl sulfide are also rather efficient, $k^S = (2-3) \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ for BQs,

NQ, and AQ in acetonitrile and roughly 5–10 times smaller for DMSO (Görner 2006a). A photoinduced methylene/AQ shuttle results in two-electron oxidation of a tertiary amine (Gun et al. 1991). The ET from TEA to triplet AQ was examined by Fourier-transform (FT) EPR spectroscopy (Beckert and Fessenden 1996, Kausche et al. 1996). Interactions between AQ and aromatic amines were also studied in micellar media (Chowdhury and Basu 2006). For MeAQ, H-transfer occurs from the methyl group to the carbonyl oxygen (Nakayama et al. 1999).

Some new photoreactions use skillfully substituted AQs (Brinson et al. 2005, Mitchell et al. 2005, Hou and Wan 2008). For example, a novel excited-state intramolecular reaction of 2-(hydroxymethyl)AQ in aqueous solution has been presented (Lukeman et al. 2002). A simple and smart oxygen sensor was developed based on the intrazeolite reactions of R-AQs (McGilvray et al. 2006). Biradical intermediates have been proposed to account for the photoproducts of 1-alkoxyAQs (Smart et al. 1997). Triplet formation for aminoAQs is not efficient, in contrast to diaminoAQs (Borst et al. 1992, Reszka et al. 1992). The properties of polymers containing in-chain quinone moieties have been outlined (Hodge and Gautrot 2009); their application potential, however, is limited by the rather low solubility.

The major photoprocess of nitroAQs is the conversion to 1-aminoAQs, and the full conversion requires six reduction equivalents (El'tsov et al. 1977, Studzinskii et al. 1978). An example is shown in Figure 28.4. The first step is population of the triplet state, which has τ_T of ca. 20 ns for 2-methyl-1-nitroAQ. H-transfer from the alcohol generates nitroAQ-derived radicals that combine bimolecularly in nitroAQ and nitrosoAQ (Gruen and Görner 2008, Görner and Gruen 2010). The reactions are summarized by step (a) in Scheme 28.3. The same radical can be produced by ET from an amine. Further ET steps occur, whereby 1-aminohydroxylAQ is formed (step b). The quantum yield of complete reduction is up to 0.2. In 1-phenylethanol, acetophenone, which acts as a sensitizer, was found as trace impurity. Various sensitizer-donor couples with ketones and alcohols or amines can likewise be used to achieve efficient conversion. For 1-nitroAQs, however, the carbonyl groups function in steps (c) and (d) as H-atom acceptor sites. The further reduction by prolonged irradiation, shown in the inset of Figure 28.4 as secondary band around 390 nm, yields the dihydro-1-aminoAQ, step (e). Admission of oxygen yields back the 1-aminoAQ, this being a common reaction of quinones.

Larger quinones partly follow a photochemical pattern analogous to that of AQ (Davies et al. 1972b, Harada et al. 2005). For 9,10-phenanthrenequinone (Taguchi et al. 2007) two close-lying triplet states were proposed (Silva and Nicodem 2008); self-quenching in acetonitrile is efficient, $k = 7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ (Yamaji et al. 2002). The rate constant of triplet quenching by 9,10-phenanthrenequinone in

FIGURE 28.4 Absorption changes at 470 nm vs. time of irradiation at 313 nm for 2-methyl-1-nitroAQ in argon-saturated acetonitrile in the presence of 1 M 1-phenylethanol; insets: spectra at 0, 240, and 400 s, 1–3, respectively, cf. Gruen and Görner (2008).

SCHEME 28.3 Photoreduction of 1-nitroAQ.

acetonitrile is $k^Q = 4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ (Nicodem et al. 2005). For 6,11-dihydroxynaphthacene-5,12-dione in acetonitrile $\Phi_f = 0.4$; an exciplex has been detected upon interaction with aromatic hydrocarbons (Rath and Mukherjee 1997, Rath et al. 2001). For 5,12-naphthacenequinone in CCl_4 , self-quenching occurs with a rate constant of $4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ (Yamaji et al. 2002). For 6-phenyloxy-5,12-naphthacenequinone the *trans*→*ana* photoreaction takes place within 15 ns via a triplet biradical, whereas the reverse photoreaction occurs via the excited singlet state (Born et al. 2007). Photochemical H-abstraction by pyrene-4,5-dione has been studied (de Lucas et al. 2009). CT properties and solvent dependence have been found for a quaterthiophene-AQ dyad (Wan et al. 2008).

A different pattern results for violanthrone (V) and 16,17- R_2Vs (Seybold and Wagenblast 1989), the reduction of which was recently studied (Gruen and Görner 2009, 2010). Due to the absence of an accessible triplet state, sensitizers, such as acetone, acetophenone, or benzophenone, were employed. The photoproducts of Vs are the fluorescing dihydroviolanthrones (VH_2s), which undergo back-oxidation to Vs on admission of oxygen. This quinone reconstitution is common for NQs and AQ (see Chapter 9). An example of the photopromoted conversion is shown in Figure 28.5. Formation of VH_2 is effected by the presence of an alcohol or TEA. The intermediacy of the semiquinone radical (VH^\bullet , Scheme 28.4a) is indicated by the formation of VH_2 within 1 ms. The back-reaction on admission of oxygen via the VH^\bullet radical is shown in Scheme 28.4b.

SCHEME 28.4 (a) Photoreduction of violanthrones and (b) oxidation of dihydroviolanthrones.

28.6 Properties of Semiquinone Radicals

Various reactions of free radicals in aqueous solution with quinones have been investigated. The literature concerning the properties of radicals derived from quinones is numerous and only a few papers can be cited here (Roginsky et al. 1998, Yashiro et al. 2005, Folkes et al. 2007). Some new data concerns *p*-quinones (Land et al. 2001, 2003). The reduction potentials and equilibria of various one-electron couples, for example, quinones and oxygen, were determined by pulse radiolysis (Meisel and Czapski 1975). Fortunately, the topic has been reviewed (Wardman 1989). The radical anion and its conjugate acid of most quinones have different maxima (λ_R) and molar absorption coefficients; some values are listed in Table 28.7. The inflection point is located at pK_a . While pK_a of BQs, NQs and AQs is at 4–5, that of riboflavin is much larger (8.3; Steenken and Neta 2003).

$Q^{\cdot-}$ of AQ has a second peak at 480 nm in contrast to $^{\cdot}QH$. Such a two-*vs.*-one peak behavior of the conjugate radicals is not known for BQs and NQs. For the reaction of semiquinone radicals of 2,5-di-*tert*-butylBQ in acetonitrile with oxygen the rate constant is small, $k = 2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ (Valgimigli et al. 2008). A molecular-level understanding of the reactivity differences for radical anions of juglone and plumbagin was approached by electrochemical methods (Hernández-Muñoz et al. 2009). The fluorescence of the radical anion of BQ in methyltetrahydrofuran at 77 K has $\Phi_f = 0.003$ and a lifetime $\tau_f = 63 \text{ ns}$ (Cook et al. 1997). The 1,2,4-trihydroxybenzenes (benzenetriols: $(HO)_3C_6R_3$) react with BQs to BQH_2 s and 2-hydroxybenzoquinones ($BQOH$ s) (Schuchmann et al. 1998). This has major consequences on the photoproduct pattern (see Chapter 7).

TABLE 28.7 Radial Maximum and Absorption Coefficient of Quinones^a

Compound	pK_a	Semiquinone Radical		Radical Anion	
		λ_R (nm)	ϵ ($10^3 \text{ M}^{-1} \text{ cm}^{-1}$)	λ_R (nm)	ϵ ($10^3 \text{ M}^{-1} \text{ cm}^{-1}$)
BQ	4.0	404	5.0	430	6.1
Me ₄ BQ	5.0	420	4.4	445	7.4

28.7 Effects of Water on the Quinone Photoprocesses

The photoreactivity of certain quinones, Me₄BQ for example, is quite similar in the absence and presence of water. A different situation holds for the photoprocesses of more reactive BQs, which give rise to 2-hydroxyBQs as additional products in water (Fukuzumi and Yorisue 1991). (HO)₃C₆H₃s are pH-dependent intermediates (von Sonntag et al. 2004). $\Phi^{\text{H}_2\text{O}}$ of substrate decomposition is large for BQs (Table 28.1) and the major part is due to formation of 2-hydroxyBQs. The values at pH 7 show some scatter, from $\Phi^{\text{H}_2\text{O}} = 0.35$ (Kurien and Robins 1970) to 0.5 (Görner 2003b). The presence of air/oxygen has only a small effect. The effect of water dominates since $\Phi^{\text{H}_2\text{O}}$ with and without 50% acetonitrile are very similar. For BQ in both water and heavy water $\tau_{\text{T}} = 0.2 \mu\text{s}$ (Yuasa et al. 2008). The pH dependence of the transient conductivity of BQ (Figure 28.6) reveals a large positive signal after a few microseconds at pH 5–8 and then the decay due to neutralization. In the basic range, a photoinduced proton is removed by reaction with OH[−] from bulk solution, resulting in a negative signal after a few microseconds, which is followed by partial decay.

The role of hydroxyl radicals in the photochemistry of BQs and NQs has been discussed (Ronfard-Haret et al. 1980). Some authors gave evidence against this (Shirai et al. 1975, von Sonntag et al. 2004) and others (Beck and Brus 1982, Ononye and Bolton 1986, Parker et al. 1992) favored it. Evidence has also been given against the formation of free hydroxyl radicals in the photochemical oxidation of water by MeBQ (Pochon et al. 2002). For Me₂BQ $\Phi^{\text{H}_2\text{O}} = 0.5$, the amount of hydroxyquinone is ca. 60% (Mazellier and Bolte 1996). The mechanism of dilute BQs does not involve free radicals at all, except at a later stage (Scheme 28.5a) where R = H, Me, or Cl. In particular, no OH radical is involved in the absence of a donor as long as self-quenching is avoided. Based on transient spectroscopy and conductivity, it could be demonstrated that the proposed pathway is initiated via nucleophilic addition of water to the lowest triplet state, reaction (7). The photohydrate (HI_{aq}) is converted to (HO)₃C₆H₃, step (8), which, in turn, generates hydroxyquinone in a thermal exchange reaction (9).

A more extended mechanism of photoreduction of parent BQ, methylBQs and chloroBQs in aqueous solution is compiled in Scheme 28.6. An important step is self-quenching, that is, reaction (11) of a quinone molecule in the triplet state with one in the ground state. A complex of such an excited BQ and a ground state BQ has been proposed, the equilibrium constant is 5500 M^{−1} (von Sonntag et al. 2004). As a consequence of reactions (11) and (12), a radical ion pair can be formed. The radical cation then reacts with water in the 2-hydroxyquinone radical, which, in turn, reacts with Q in hydroxyquinone and QH₂. The hydroxyphoto-product is spectroscopically accessible, the anion has $\epsilon_{500} = 2 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ and $\text{p}K_{\text{a}} = 4.2$. The formation of a (HO)₃C₆H₃ intermediate has independently been published for 2,6-Cl₂BQ, where $\Phi^{\text{H}_2\text{O}} = 1.5$, the amount of hydroxyquinone is ca. 40% and QO[−] is observable with $\epsilon_{524} = 2.5 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ (Lente and Espenson 2004). Mono-, di-, and trichloroBQs were recently studied (Görner and von Sonntag 2008) and examples

of the spectra and kinetics including a transient conductivity signal are shown in Figure 28.7. For ClBQ and Cl_3BQ $\Phi^{\text{H}_2\text{O}} = 0.3 - 0.4$, respectively. BQ in aqueous acid can be photohydrated (Ramseier et al. 2003). The Marcus inversion region of ET between excited quinones and amines has been studied in micellar media (Satpati et al. 2008).

Analogously, the photoprocesses of dilute aqueous NQ solutions do not involve free radicals (Brahmia and Richard 2005). The mechanism is shown in Scheme 28.5b. Trihydroxynaphthalene ($(\text{HO})_3\text{C}_{10}\text{H}_5$)

is the pH-dependent intermediate and juglone the additional photoproduct in water, the contribution changes from $\Phi^{\text{H}_2\text{O}} = 0.03$ at pH 7 to 0.8 at pH 2.4 (Brahmia and Richard 2003). The increase of $\Phi^{\text{H}_2\text{O}}$ on going to the acidic pH has also been found for MeNQ (Görner 2005a). The rate constant of triplet self-quenching is $k_{11} = 4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ (Loeff et al. 1991); that is, it is difficult to avoid formation of the radical pair (see the corresponding case, steps (11)–(13) in Scheme 28.6). The photolysis of vitamin K₃ has been examined (Chen et al. 1999). The rate constant for H-transfer from lysozyme to triplet NQ is $k^{\text{lys}} = 2.4 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ (Zhang et al. 2008). Menadione (2-MeNQ) is a frequently utilized sensitizer for the initiation of strand breaks in DNA and polynucleotides; an easily overlooked secondary process is cross-linking (Melvin et al. 1996, Bergeron et al. 2007). NQs were employed for the analysis of the interaction with bases and DNA components (Bose et al. 2008, 2009). Evidence was given by FT infrared spectroscopy for an intramolecular H-transfer in NQ as well as ubiquinone and plastoquinone (Burie et al. 1995). For 5-MeNQ, photoenolization and enol trapping takes place (Chiang et al. 1997).

AQs in aqueous solution are the subject of intensive photochemical investigations (Goez 1990, Goez and Sartorius 2003, Forbes et al. 2006, Roth 2006). Photohydrates are formed and the product pattern, for example, mono- and di-hydroxyAQs, is different, when water is present; $\Phi^{\text{H}_2\text{O}} = 0.08$ for HOAQ (Broadbent and Newton 1972, Broadbent et al. 1975). The involvement of hydroxyl radicals in the photochemistry of AQs has been discussed (Clark and Stonehill 1972, Moore et al. 1986) and later disregarded (Loeff et al. 1983, 1984). The rate constant for deprotonation of the semiquinone radical of sulfonated AQ in acetonitrile/2-propanol increases with the water content (Wakisaka et al. 1987). A 1,5-disulfonatedAQ/TEA couple was used to examine two-photon ionization with 308 nm pulses; one photon produces the radical anion via ET and the second ejects a hydrated electron (Goez and Zubarev 1999).

ET occurs from thymine or amino acids to triplet excited AQs (Geimer et al. 1997, Geimer and Beckert 1998, Tarábek et al. 2006). For α -glycine as amino acid, decarboxylation was observed by FT-EPR (Lü et al. 2001). A thymine dimer can be oxidatively cleaved by ET to excited AQ (Sheng et al. 2004). Under certain conditions, photoamination of AQ takes place (Tajima et al. 2009). The photochemistry of NQs in cyclodextrins (Takamori et al. 2001) and of AQs in liposomes (Moribe et al. 2008) has been studied by time-resolved EPR spectroscopy. AQs efficiently function as sensitizers of polynucleotides and their components (Bose et al. 2008, 2009) as well as for the initiation of damage in DNA (Armitage et al. 1994, Schuster 2000). The photoreduction of parent AQ is also efficient in hydrogels that are swollen with water and 2-propanol (Foyle et al. 1992).

28.8 Effects of Quenchers

Several aspects of the ET process from amino acids to triplet quinones have been studied. For *N*-acetyltyrosine (NaTyr), some rate constant values are listed in Table 28.5. While the rate constant of triplet quenching by phenylalanine, tyrosine, and tryptophan is close to the diffusion-controlled limit, those of aliphatic amino acids are several orders of magnitude smaller; no reaction can take place for quencher concentrations in the mM range and their Φ_{d} are therefore negligible. A decarboxylation has been revealed in a FT-EPR study after ET from α -amino acids to triplet AQs (Tarábek et al. 2007). A tyrosyl radical and semiquinone charge pair was detected upon ET in photosystem II at low temperatures (Zhang et al. 2004).

The ET reactions from ascorbic acid to ^3Q of a series of quinones were observed under oxygen-free conditions; H-abstraction was proposed in water-free solution (Bisby and Parker 1995), but this is unlikely, especially in water. The deprotonated ascorbate and the acid are in equilibrium with $\text{p}K_{\text{a}} = 4.15$. Therefore, without buffer Asc^- and AscH are present at lower and higher concentration, respectively. $\Phi^{\text{AscH}} = 0.1\text{--}0.6$ for methylBQs but relatively small for AQ (Table 28.1). The reactivity k^{AscH} is sufficiently large for AscH and most quinones (Table 28.5). The photoinduced mechanism involves semiquinone radicals and leads to the hydroquinones (steps (3) plus (5), Scheme 28.7). For comparison, Φ^{DABCO} is lower than 0.03, that is, ET from DABCO does not yield much QH_2 in contrast to ascorbic acid. AscH is unique in the respect that a reduction step of the semiquinone radical, analogous to step (6), does not occur. Instead, the radicals

SCHEME 28.7 Oxidation of ascorbic acid via triplet quinines.

recombine to deoxyascorbate and AscH. Interestingly, k^{TEA} of triplet quinones is much lower in neutral than strongly basic solution (Scaiano and Neta 1980), in contrast to EDTA, which has no significant pH effect. Formate functions as efficient H-donor, but the rate constant is lower than the diffusion-controlled reaction, for example, $k^{\text{For}} = 2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ for AQ (Loeff et al. 1991).

ET from dimethyl sulfide and DMSO to ^3Q is rather efficient for chloroBQs and AQ (Görner 2006a). Methides are also quenched by DMSO (Swartz et al. 2008). The oxidation of DMSO has been used in the analysis of the photoprocesses of Cl₂BQ (Lente and Espenson 2004). The photoreactions with DMSO were not unambiguous. It had been argued that DMSO is not a physical quencher and plays a certain role in the generation of hydroxylation intermediate (Pochon et al. 2002). However, the proposed intermediacy of a kind of krypto radical, that is, OH radicals complexed to the semiquinone radical (Gan et al. 2008), has been ruled out since *tert*-butanol has no effect on the BQ/DMPO-spin-trap system upon irradiation. This is in contrast to the well-known scavenging behavior against hydroxyl radicals, excluding that the precursor is formed via $\cdot\text{OH}$ attack (von Sonntag et al. 2004). The mechanism of the photoreactions of MeBQ has recently been modified (Gan et al. 2008) and is open to further discussion. The AQ-sensitized photoconversion of oxygen in hydrogen peroxide is quenched by DMSO (Garg et al. 2007).

28.9 Triplet State Reactions Involving Singlet Oxygen or O₂^{•-} Radicals

Triplet quenching by oxygen is less efficient for BQs in aqueous solution than in organic solvents, but significant for most quinones. The rate constant of reaction of singlet molecular oxygen with BQ is much smaller, for example, $k = 4.6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ in acetonitrile (Gutiérrez 2008) and the data of Φ_{Δ} (Alegria et al. 1997, 1999, 2002) have been reviewed (Redmond and Gamlin 1999). For juglone, $\Phi_{\Delta} = 0.14$, but $\Phi_{\Delta} < 0.01$ for lawsone; some values are listed in Table 28.6. The admission of oxygen reverts QH₂ back to NQs or AQs.

The photooxidation of 5-OH-1-naphthol to juglone has frequently been studied (Brahmia and Richard 2005, Oelgemöller et al. 2007). Juglone serves as a valuable building block for the synthesis of biologically active quinoids. The photoinduced key step is reaction (a) of the substrate with singlet molecular oxygen, in which the latter is produced via energy transfer from a triplet sensitizer. The product is formed after rearrangement (b) and release of water. AQ is one photoproduct of anthracene in air-saturated aqueous solution; no external sensitizer is required, but an endoperoxide is also the intermediate, similar to reactions a and b in Scheme 28.8 (Alegria et al. 2004). Singlet oxygen and radical reactions were examined in various systems, for example, by diaminoAQ-photosensitized oxidation of human

SCHEME 28.8 Photoreactions of TQ.

leukemic cells (Reszka et al. 1988, 1992). In water, the role of the superoxide ion $O_2^{\bullet-}$ and the hydroperoxyl radical HO_2^{\bullet} , the conjugate acid with $pK_a = 4.8$, is to be considered (von Sonntag 1987, 2006, Cabelli 1997, Bobrowski et al. 2007).

Self-quenching of a triplet state (11) (see Scheme 28.6) and the subsequent reaction of the radical anion with oxygen can lead to formation of $O_2^{\bullet-}$. This is in competition to the formation of singlet molecular oxygen, which may also play a role in aqueous solution. The yield of $O_2^{\bullet-}$ can be strongly enhanced by ET from a donor. Alternatively, H-transfer can be employed (Wilkinson 1962). The hydroperoxyl radical can easily be converted into hydrogen peroxide, thereby consuming oxygen. The reactions become more complex, when appropriate donors are present. Photoinduced oxygen uptake was studied for BQs, NQs, and AQs using several donors, including aromatic amino acids. The reactivities of some donors in acetonitrile–water (1:1) are similar to those in Table 28.6 without water. Examples of the weak (Me_4BQ) and strong ($BrNQ$) oxygen uptake as a function of the time are shown in Figure 28.8.

The mechanism in the presence of formate, ascorbic acid, alcohols, and amines is summarized in Scheme 28.9 (Görner 2004b, 2006b, 2007a,b). The reaction is initiated by triplet quenching (3), oxygen then reacts with the semiquinone radical (forward step in equilibrium (14)), and eventually, the hydroperoxyl radical terminates to hydrogen peroxide (15). Large differences in the constant K_{14} are known for BQ vs. AQ or NQ, the equilibrium lies on the BQ side, but in the cases of NQ and AQs on the HO_2^{\bullet} side. If Φ_{isc} is close to unity, the quantum yield of oxygen uptake (Φ_{-O_2}) can approach 0.5–0.9 (Table 28.8). With ascorbic acid (Roginsky et al. 1999, Roginsky and Barsukova 2000), each hydroperoxyl radical is

Görner (2007b).

converted to hydrogen peroxide, in contrast to other donors. Plots of Φ_{-O_2} as a function of the log of the donor concentration are shown in [Figure 28.9](#). Differences in the rate constants are the main reason for the shift of the curves. The role of singlet oxygen versus radical peroxidation in the photooxidation of human blood plasma has been analyzed (Barclay et al. 2003). AQ is the major photoproduct of anthracene in air-saturated aqueous solution (Sigman et al. 1991).

28.10 Effects of Side Groups

Most quinones so far presented do not have side chains. One exception refers to the ubiquinone moiety and another to plastoquinones or lapachol. Vitamin K₁ contains a isoprenoid chain and, in contrast to other quinones without an olefinic chain, intramolecular H-atom and/or CT processes from the isoprenoid group take place. The photoreactivity of vitamin K compounds has been examined (Hangarter et al. 2003, Swartz et al. 2008) and the mechanism of vitamin K₁ is shown in Scheme 28.10a. The products have been characterized as *E* and *Z* tautomers of 1,2-quinone methide (1,2-QM) and two 1,3-quinone methide diradicals (1,3-QM) as intermediates. The rate constant of quenching of 1,3-QM in acetonitrile is $5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. The mechanism for lapachol is very similar (Görner 2004a, Scheme 28.10b). Intramolecular H-transfer from the side chain to the NQ moiety has also been found for 5-ethylene-2-ylNQ, a product is a 5-vinylNQ (Balakrishnan and Umapathy 1999).

Other quinones with side chains are 2-Me-5-isopropylBQ: thymoquinone (TQ), the 2,5-dibromo derivative (Br₂TQ), and 2-*tert*-butylBQ. Intramolecular proton/H-transfer successfully competes with

SCHEME 28.10 Photoprocesses of (a) vitamin K₁ and (b) lapachol.

SCHEME 28.11 Photoprocesses of thymoquinone.

intermolecular photoprocesses. Φ of photodecomposition of the three BQs is large in neat acetonitrile and other solvents even in the presence of oxygen. The mechanism is shown in Scheme 28.11. The first short-lived transient of Br₂TQ with a lifetime of 0.02–0.1 μ s is assigned to the triplet state (see Figure 28.10). This is in contrast to 2-*tert*-butylBQ, where no intermediate could be detected under comparable conditions, and to TQ, where a different mechanism operates. The effects of solvent polarity and other

FIGURE 28.10 Transient absorption spectra of Br₂TQ in argon-saturated acetonitrile (a) dry and (b) plus 1 M water at 20 ns, 0.1 μ s, and 10 μ s after the 308 nm pulse; insets: kinetics as indicated, cf. Görner (2005b).

specific properties of intramolecular H-transfer with TQ and Br₂TQ were described. $\Phi_{\Delta} = 0.2\text{--}0.3$ for Br₂TQ in CCl₄ and acetonitrile but nearly zero for TQ (Görner 2004c, 2005b). The triplet state of Br₂TQ converts into a zwitterion, which is formed after intramolecular H-transfer from the side chain. Further conversion into hydroquinones, not involving free radicals, is proposed. For Cl₂BQs, which are 3,6-substituted by aliphatic amino acids, biradical zwitterions and intramolecular trapping of an excited CT state have been suggested (Jones and Qian 1998). Drastic differences in lifetimes of the charge-separated state were found for a formanilideAQ versus the ferrocene-attached AQ (Okamoto et al. 2005). A reaction mechanism of a photoremovable protecting group based on NQ has been proposed (Kamdzhilov and Wirz 2007).

28.11 Biological Aspects

The role of quinones in photosynthetic reaction centers has been addressed by various groups (Antolovich et al. 1991, Johnson et al. 1993, Kurreck et al. 1995, Macpherson et al. 1995, Fajer et al. 1996, Murtinho et al. 2000, Springer et al. 2003, Osyczka et al. 2006, Barbafina et al. 2008) but is only briefly touched upon here. Especially the cascade reactions of excited pigments, for example, porphyrins, linked to quinones were investigated. Modeling of the ET in photosynthetic systems over a long range is based on rigidly bridged donor–acceptor, for example, porphyrin–quinone pairs, the topic has been reviewed (Verhoeven 2006). Alternative electron donors are ruthenium salts (Borgström et al. 2003, Benniston et al. 2005). Hydrogen bonding to quinones (Biczók et al. 1994) was found in virtually all bacterial reaction centers. The remarkably high efficiency of photosynthesis is based on light harvesting by the (bacterio)chlorophyll antenna system. The energy is transferred to the reaction center from where electrons are passed to noncovalently attached quinones. The redox properties are of great importance when mimicking the primary photochemistry of pigment/quinone-type reaction centers. The quinoid end groups of a carotenoid, in contrast to phenolic groups, were found to be fully integrated into the conjugation system (Marian et al. 2009).

One model system consists of zinc *meso*-tetrakis(sulfonatophenyl) porphyrin and UQ₀; it undergoes ET in both the triplet and the excited singlet state. Quenching of excited porphyrins by BQs has been analyzed via optoacoustic spectroscopy (Malkin et al. 1994, Yeow and Braslavsky 2002, Andres et al. 2006). Accelerating effects of ammonium cations on the ET of triplet porphyrin to BQ or NQ have been reported (Okamoto et al. 2004). Other systems contain chlorins, for example, Zn-chlorin-6. Scheme 28.12 shows the reactions involved in fast ET from a singlet excited chlorin to a quinone (Mennenga et al. 2006). The quinone quenches the first excited chlorin state (¹*P) and the lowest triplet state (³*P) by formation of the correlated radical pairs: ¹(P^{•+}..Q^{•-}) and ³(P^{•+}..Q^{•-}), where the former is only involved at high BQ concentrations. A direct ET from the ³*P state to a quinone can be observed by transient absorption spectroscopy, whereby the rate constant for the triplet decay and the appearance of the radical cation P^{•+} should be the same. Some photoprocesses of other

SCHEME 28.12 Photoprocesses of chlorines.

tetrapyrroles and related chromophores with quinones in solution have been examined in great detail. These investigations have revealed a broad variation of interactions and reactivities.

Much effort has been made to mimic the function of reaction centers in peptide models (Singh et al. 2007). De novo design of quinoproteins is possible (Li et al. 2006). Incorporation of metallochlorins into de novo synthesized proteins provides the possibility to study the photochemical reaction of monomeric chlorins, and upon addition of an electron acceptor, to mimic biological ET proteins found in photosynthesis and respiration. Intramolecular photochemical ET takes place for stabilized charge separation in linked porphyrin–quinone molecules (McIntosh et al. 1983). The low-temperature EPR spectroscopy of quinones and radical pairs in photosynthesis has been improved (Burghaus et al. 1993), reviewed (Lubitz et al. 2002), and updated (Sinnecker et al. 2006). The role of reaction centers containing BQs, NQs, or AQs in the place of ubiquinone has been examined (Woodbury et al. 1986). An identification of FT infrared bands is due to internal water molecules around the quinone binding sites in the reaction center from *Rhodobacter spaeroides* (Iwata et al. 2009). Several updates concerning photosynthesis are available (Gust et al. 2005, Arellano et al. 2007, Renger and Renger 2008, Barber 2009).
